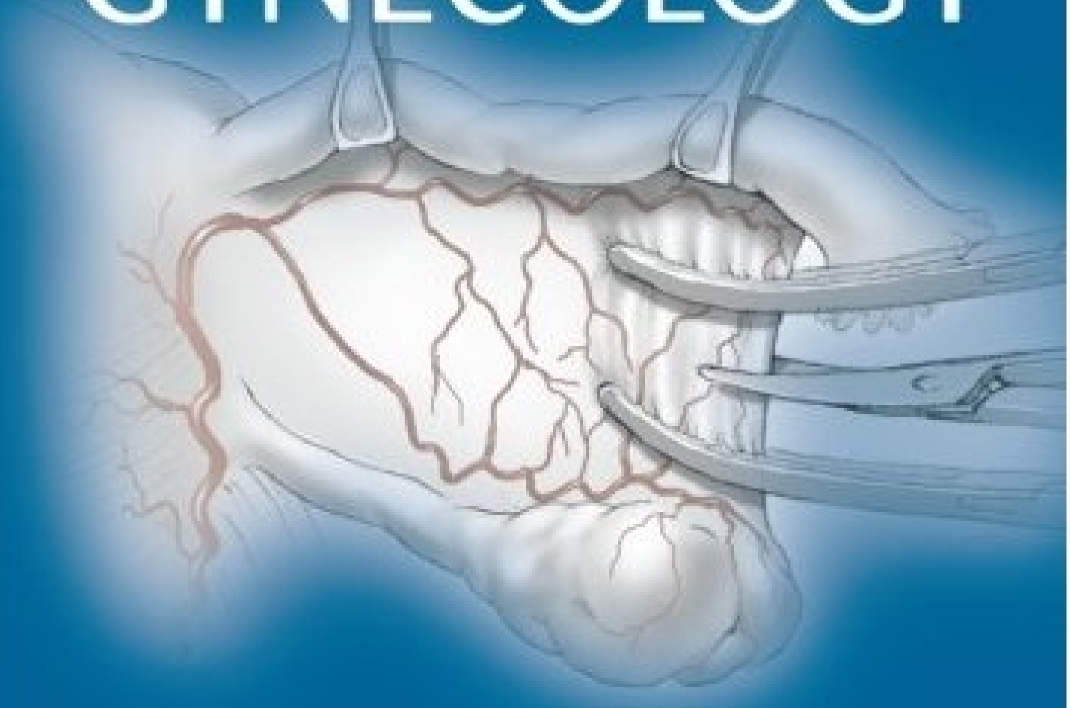
Williams GYNECOLOGY



Preface

The first edition of *Williams Obstetrics* was published over a century ago. Since then, the editors of this seminal text have presented a comprehensive and evidence-based discussion of obstetrics. Patterned after our patriarch, *Williams Gynecology* provides a thorough presentation of gynecology's depth and breadth. In Section 1, general gynecology topics are covered, whereas Sections 2 through 4 offer content on the gynecologic subspecialties. Of note, the developing field of female pelvic medicine and reconstructive surgery is presented.

Traditionally, gynecologic information has been offered either within the format of a didactic text or that of a surgical atlas. However, because the day-to-day activities of a gynecologist blend these two, so too do we. The initial five sections of our book describe the evaluation and medical treatment of gynecologic problems. The remaining section offers an illustrated atlas for the surgical correction of these conditions. Discussions of disease evaluation and treatment are evidence based, and our text strives to assist the practicing gynecologist and resident. Accordingly, chapters are extensively complemented by illustrations, photographs, diagnostic algorithms, and treatment tables.

Artists

Artist renderings in our surgical atlas were produced by Lewis Calver, the Chairman of the Biomedical Communications Graduate Program, and students and faculty within that program.

The world's first degree in medical illustration was awarded by Southwestern Medical School in 1947. This is one of five accredited medical illustration programs in North America. For those accepted into the program, a Master of Arts degree in Biomedical Communicationsâ€”Biomedical Illustration is offered by Southwestern Graduate School of Biomedical Sciences at The University of Texas Southwestern Medical Center. The program is two years in length and a maximum of seven students is now enrolled annually.

The program is offered through the Department of Biomedical Communications, and courses are taught by faculty of The University of Texas Southwestern Medical School, Southwestern Graduate School of Biomedical Sciences, and Southwestern Allied Health Sciences School. The program is accredited by the Commission on Accreditation of Allied Health Education Programs and the Association of Medical Illustrators. Mr. Lewis E. Calver has been Program Chairman since 1980.

The program is interdisciplinary. It is designed to provide opportunities for development of special knowledge and skills in the application of communications arts and technology to the health sciences. Study of human anatomy, cell biology, neurobiology, and pathology is combined with experience in anatomical, surgical, editorial and advertising illustration, computer graphics and animation, graphic design, multimedia production, interactive computer assisted instruction, and instructional design. Additional skills may also be developed in biological illustration, three-dimensional media production, exhibit design, and photography.

Overview

Human immunodeficiency virus (HIV) infected women are known to have a high burden of human papilloma virus (HPV)-associated anogenital disease. This lower genital tract disease manifests as a spectrum of lesions, which ranges from condyloma to high-grade, high-malignant potential cervical intraepithelial neoplasia (CIN), vulvar intraepithelial neoplasia (VIN), and anal intraepithelial neoplasia (AIN) lesions.

The association between cervical dysplasia, cervical carcinoma, and human papilloma virus (HPV) infection is clearly established (Bosch, 2002). However, the etiologic contribution of human immunodeficiency virus (HIV) in the development of lower genital tract disease is unclear and currently under evaluation. Specifically, areas of attention include the effect of HIV serostatus in the acquisition, regression, persistence, or progression of HPV infection. The relationship between HIV and HPV infections may involve mechanisms that integrate virus to virus interactions, immune factors, and molecular pathogenesis, and all of these mechanisms can impact normal cell cycle machinery (Clarke, 2001).

Although evidence to date establishes HPV as the etiologic agent causing cervical intraepithelial and invasive neoplasia (Mahdavi, 2005), HPV infection is generally uneventful and transient in HIV-seronegative women. In contrast, recent studies have shown that HIV-positive women have a higher prevalence and longer persistence of cervical HPV infection. HPV is detected in more than 60 percent of women with HIV (Stover, 2003). In addition, these women have a higher probability of carrying multiple oncogenic HPV types than that of HIV-negative women (Ahdieh, 2001; Brown, 1994; Palefsky, 1999).

The effects of HIV can also be seen in the rates of disease progression. For example, early during the acquired immune deficiency syndrome (AIDS) epidemic, Maiman and colleagues (1990) noted in a study cohort that all HIV-positive women with cervical cancer died from their cancer compared with only 37 percent of HIV-seronegative women with cervical cancer. Because of this and similar studies, cervical cancer is now designated as an AIDS defining condition by the Center for Disease Control and Prevention.

Lower Genital Tract Intraepithelial Neoplasia

Studies consistently suggest that HIV-positive women have much higher rates of CIN compared with HIV-uninfected women (Ellerbrock, 2000; Wright, 1994). For example, in women infected with HIV, up to 60 percent of Pap smears exhibit cytologic abnormalities, and as many as 40 percent have colposcopic evidence of dysplasia. Maiman and associates (1998) report that these rates are approximately 10 times greater than those observed among HIV-negative women.

In contrast, much less information is available regarding vulvar, vaginal, and anal intraepithelial neoplasia in these women. However, a recent 6-year prospective study did compare HIV-positive with HIV-negative women at high risk for HIV and found an eightfold increase in the rates of vulvar, vaginal, and perianal lesions in HIV-positive women (Jamieson, 2006). Moreover, Chin-Hong and associates (2005) found a higher prevalence of HPV-associated anogenital disease in women with HIV compared to age-

matched HIV-negative controls. Specifically, in women with HIV, higher rates of anal HPV infection and increased rates of infection with oncogenic HPV types have been noted (Palefesky, 2000; Sun, 1997). A cross-sectional study of women reported 76 percent of HIV-positive and 42 percent of HIV-negative women had anal HPV DNA by PCR. Furthermore, 26 percent of 251 HIV-positive women were diagnosed with AIN compared with 8 percent of 68 HIV-negative women (Palefsky, 2000).

In general, lower genital tract disease risk factors in women with HIV were found to be similar to those for CIN. Risks included a CD4+ count less than 200 cells/ÂµL and the presence of HPV DNA (Jamieson, 2006). Similarly in these women, studies report that decreasing CD4+ and increasing viral load counts also correlate with the detection and increased prevalence and persistence of HPV infection (Palefsky, 1999; Strickler, 2005).

Cervical Cytology Screening

It is unclear whether the degree of immunosuppression in women with HIV infection correlates with the progression of abnormal cervical cytology. Specifically, investigations suggest that high viral loads may result in escalated cytologic abnormalities. Cardillo and colleagues (2001) recently examined the association between cervicovaginal Pap smears from HIV-positive women and their CD4+ counts and HIV viral load. This review of 108 HIV-positive women found the degree of immunosuppression may contribute to the development of intraepithelial lesions (Cardillo, 2001). In addition, higher rates of CIN postconization recurrence have been observed among HIV-positive women, and those who showed a recurrence of dysplasia were more likely to have failed highly active anti-retroviral therapy (HAART) than those without recurrence (Gilles, 2005).

Decreased Pap smear sensitivity or specificity has not been demonstrated between HIV-positive and HIV-negative women (Spinillo, 1998). Because HIV infection is linked to a significantly higher risk of developing squamous intraepithelial lesions, cervicovaginal cytologic screening should be obtained every six months for the first year after an HIV infection diagnosis (Byrne, 1989). With normal cytology, annual screening for life is recommended. In addition to vigilant cervical cytologic testing, women with HIV may benefit from routine anal Pap screens to monitor for AIN (Palefsky, 2001).

Abnormal Cytology Management

Any cytologic abnormality is an indication for colposcopic evaluation. This includes atypical squamous cells of undetermined significance (ASC-US), the mildest cytologic abnormality defined in the Bethesda nomenclature system. In a study of women with ASC-US, Wright and co-workers (1996) reported that HIV-positive women were twice as likely to have underlying dysplasia compared with HIV-negative women. Given the increased frequency of cytologic abnormalities and the increased possibility for underlying dysplasia with a single ASC-US Pap smear, HIV-positive women require colposcopic evaluation of any atypical cells. HIV-positive women with dysplasia of the cervix are often found to have extensive dysplastic epithelial disease throughout the lower genital tract including the vagina, vulva, and anus (Hillemanns, 1996). Therefore, any abnormal cytology warrants colposcopy of the entire lower genital tract.

Treatment

Ablative therapy is not recommended for HIV-positive women with biopsy proven lower genital tract disease. Excisional procedures including loop electrosurgical excision procedure (LEEP), carbon dioxide laser, or cold-knife conization provide histologic margins for evaluation. Although excisional therapy is effective for eradicating CIN in immunocompetent patients, the same treatment seems to be effective only in preventing progression to cancer in HIV-infected women (Heard, 2005). Moreover, recurrence rates for excised lower genital tract disease are higher in women with HIV compared with those without HIV infection.

Effects of Highly Active Anti-Retroviral Therapy

Because of effective highly active anti-retroviral therapy (HAART), AIDS patients are living longer and expressing greater life satisfaction. However, the therapeutic impact of HAART on HPV infection is poorly understood and conflicting results have been reported (Heard, 2004). Cervical HPV and CIN are increased in HIV-positive women compared with risk-matched HIV-negative controls, and HAART appears to have only limited ability to eradicate HPV infection and induce regression of CIN (Palefsky, 2003). Immune restoration with HAART is insufficient to clear HPV as persistent HPV DNA remains detectable in most patients taking HAART (Heard, 2004). Moreover, multiple studies report a 62 to 73 percent recurrence rate for CIN after removal of the squamocolumnar junction in HIV-positive women despite HAART (Holcomb, 1999; Tate, 2002). However, Heard and colleagues

(2005) found this antiviral agent may have a strong positive impact on the recurrence rate of CIN after surgery and may delay the recurrence of HPV-related disease.

To date, HAART has not been shown to consistently improve the natural history of HPV-related diseases. Indeed, if HAART leads to increased longevity yet does not alter the incidence or progression of HPV-related disease, individuals on HAART may have sufficient time to develop HPV-related epithelial cancers (de SanjosÃ©, 2002).

7/17/2007: MCINDOE VAGINOPLASTY FOR NEOVAGINA CREATION

BARBARA L. HOFFMAN

UNIVERSITY OF TEXAS SOUTHWESTERN MEDICAL CENTER AT DALLAS

Introduction

Creation of a functional vagina is the treatment goal for many women with congenital agenesis of the vagina. Although several surgical and nonsurgical approaches have been used, the McIndoe procedure is the most commonly employed in the United States. With this technique, a canal is formed between the urethra and urinary bladder anteriorly and the rectum posteriorly (McIndoe, 1938). A skin graft obtained from the patientâ€™s buttock, thigh, or inguinal regional is then wrapped around a soft mold and placed into the newly created vagina to allow epithelialization. Alternatively, other materials have been used to line the neovagina and include amnionic membrane, cutaneous and myocutaneous flaps, buccal mucosa, and Interceed absorbable adhesion barrier (Ethicon, Somerville, NJ) (Ashworth, 1986; Lin, 2003; Motoyama, 2003; McCraw, 1976).

Preoperative Considerations

Patient Selection. Vaginal stricture can be a significant complication following the McIndoe procedure (Alessandrescu, 1996). Thus, adherence to a postoperative regimen of vaginal dilatation is mandatory. For this reason, surgery may be postponed until the patient has reached a level of maturity to comply (American College of Obstetricians and Gynecologists, 2002).

Consent. Prior to surgery, patients should be informed of overall success rates with this procedure. In the Mayo Clinic series of 225 patients, the McIndoe procedure provided a functional vagina to afford â€œsatisfactoryâ€• intercourse in 85 percent of patients. In this review, the cumulative complication rate was 10 percent and included vaginal stricture, pelvic organ prolapse, graft failure, postcoital bleeding, and fistulas involving either the bladder or rectum (Klingele, 2003). Additionally, complications at the skin graft harvest site involved cheloid formation, wound infection, and postoperative dysaesthesias.

Patient Preparation. Intravenous administration of a second-generation cephalosporin such as cefoxitin 2g in a single preoperative dose is recommended. Bowel preparation is completed the evening prior to surgery.

Intraoperative Considerations

INSTRUMENTS

Electrodermatome. The skin grafts used to line the neovagina are harvested from the donor site with the aid of an electrodermatome, which is able to shave grafts of varying size and depth. Both split-thickness and full-thickness skin grafts have been used in the McIndoe procedure, and the electrodermatome settings are adjusted to shave the desired depth.

Vaginal Mold. Following graft harvesting and neovagina formation, a stent is needed to apply the graft to the vaginal walls and hold it in place. Both soft and rigid forms have been used. Rigid mold materials have included balsa wood, pyrex, plastic, and synthetic silicone-based materials (McIndoe, 1938; Ozek, 1999; Seccia, 2002; Yu, 2004). Unfortunately, rigid or semi-rigid stents have led to graft loss, fibrosis, contracture, and pressure-related bladder or rectal fistulas. Use of soft stents has decreased the number of these complications. Inflatable rubber stents or condoms filled with foam rubber or other soft compressible materials are examples (Adamson, 2004; Barutcu, 1998; Concannon, 1993). The vagina graft produces abundant exudates and poor drainage may lead to graft maceration, sloughing, and graft detachment. Accordingly, suction has been attached to the soft stents to aid drainage of the neovagina (Yu, 2004).

Postoperative Considerations

A soft stent and Foley catheter are left in place for 7 days following surgery. To minimize dislodgement of the mold and wound contamination, a low-residue diet and loperamide, 2 mg bid orally, is used to limit defecation.

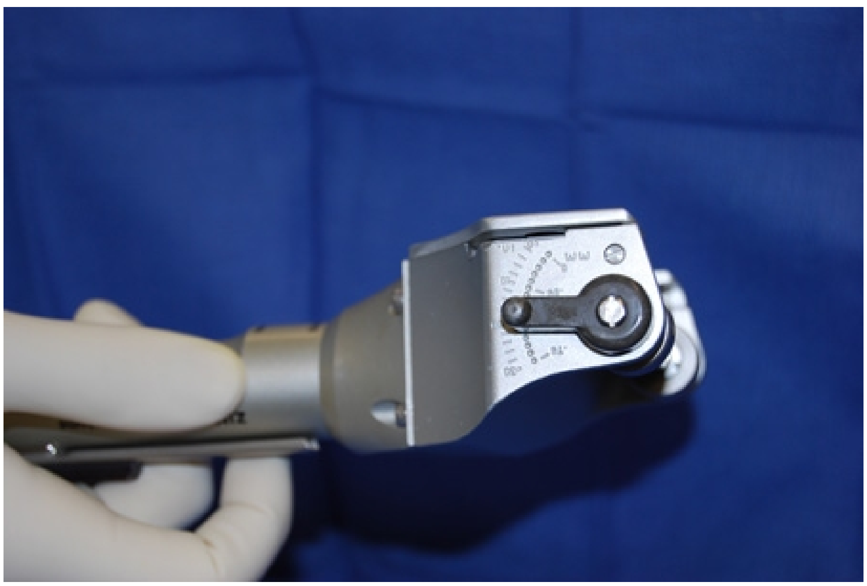
At the time of mold removal, an operating room, general anesthesia, and dorsal lithotomy position are employed. Stitches in the labia minora are cut and the mold is removed. To lessen the risk of graft avulsion, irrigation is used to reduce adherence between graft and stent. Commonly the size of the mold placed at surgery is too large for maintenance use. Therefore a smaller mold may initially be used and then gradually replaced with larger ones as the vagina stretches.

Several schedules for postoperative dilatation have been described. For the first 6 weeks following surgery, the dilator is worn continuously except during defecation. During the subsequent 6 weeks, it is used only at night. Following these initial 3 months, patients are then instructed to either wear the dilator at night or engage in intercourse twice each week.

General anesthesia is administered and the patient is positioned supine for skin graft harvesting from the thigh. Alternatively, the graft may be taken from the buttock, hip, or inguinal area. Goals of harvesting are to choose a location which has minimal hair growth and is cosmetically discreet. The assistance of a plastic surgeon may be enlisted for skin graft procurement.

The surgeon first marks the outline of the wound on the skin of the donor site, enlarging it by 3 to 5 percent to allow for skin shrinkage immediately after excision.

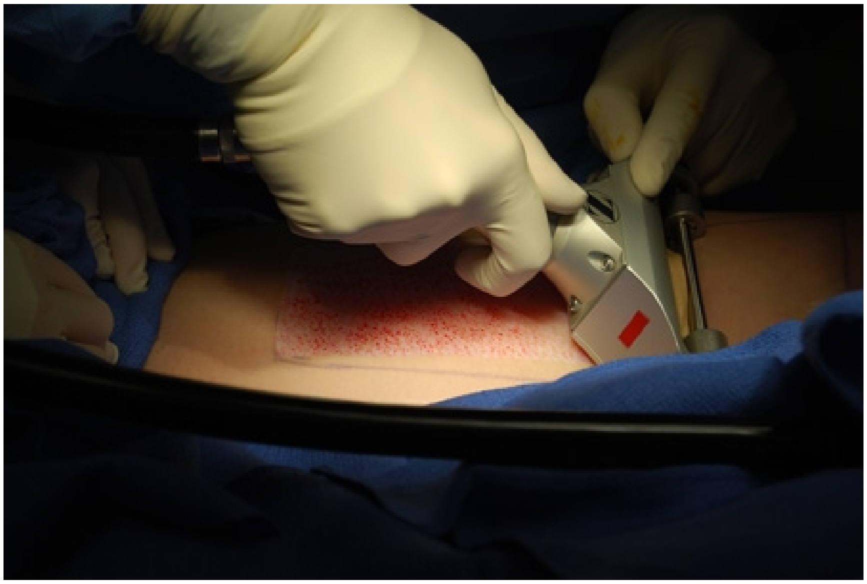
Electrodermatome.



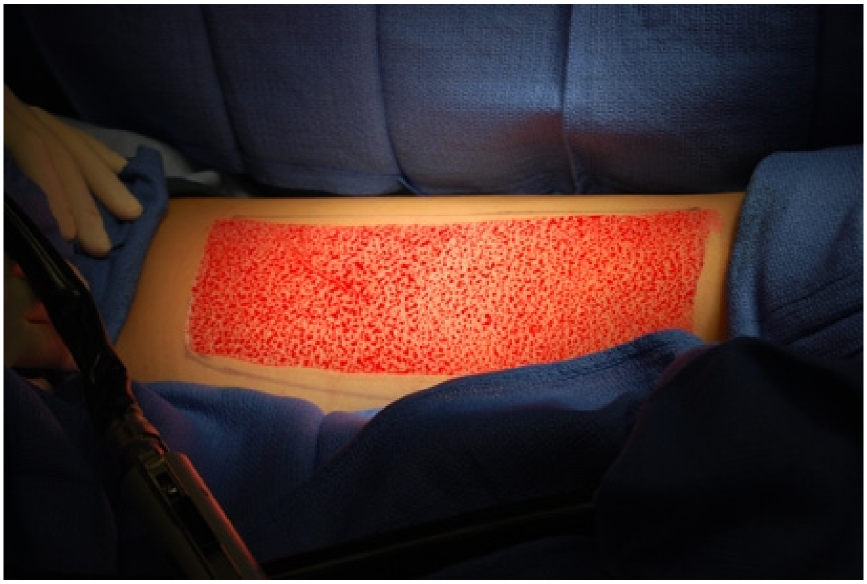
Graft thickness is preselected.

The surgeon uses the electrodermatome to remove a single strip of skin that is typically 0.018 inch thick, 8 to 9 cm wide, and 18 to 20 cm long. Alternatively, 2 smaller strips of 5 cm by 10 cm can be obtained from each buttock.

The graft is collected in front of the electrodermatome.

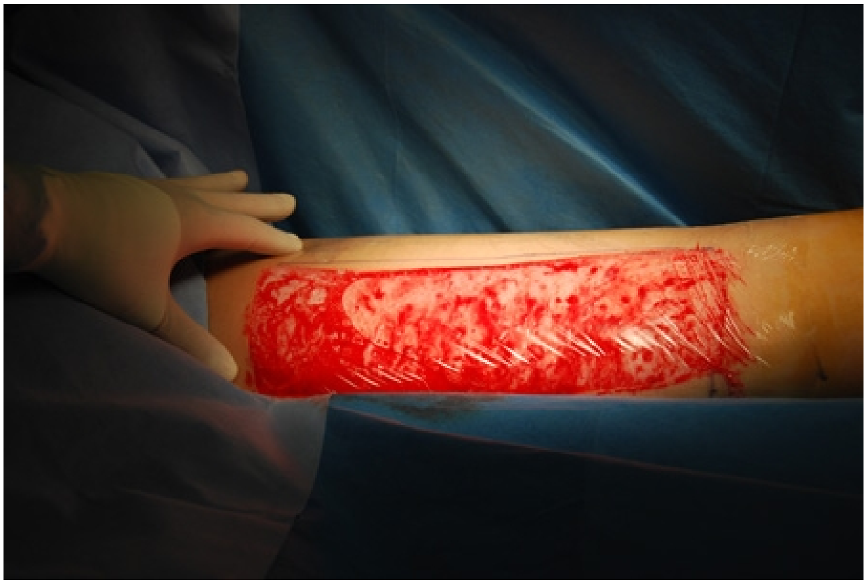


The graft is removed from the dermatome.



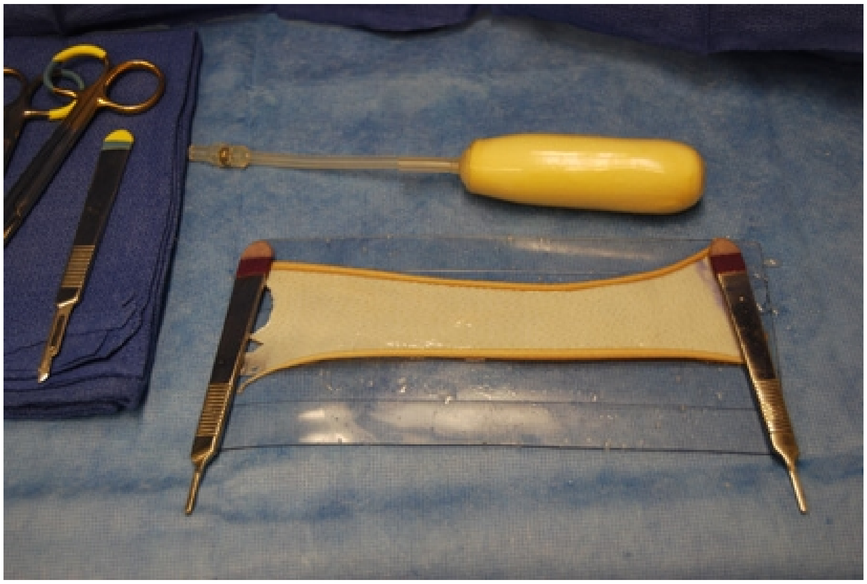
Graft harvest site immediately after harvesting.

Harvest site wound care.



The harvest site is dressed with a Tegaderm dressing.

Following excision, the graft is placed in a pan of sterile saline.



This picture displays the unrolled graft (below) and the soft mold (above). Note the suction tubing leaving the end of the soft mold. Adequate drainage of excess fluid from beneath the graft and from the vagina prevents tissue maceration and improves graft adherence.

The graft is scored to allow drainage once in place. Elimination of excess fluid from beneath the graft promotes its adherence to the vaginal walls.

One end of the graft is placed at the base of the mold, and the graft is then draped up and over the mold tip.

The external surface of the skin faces the mold.

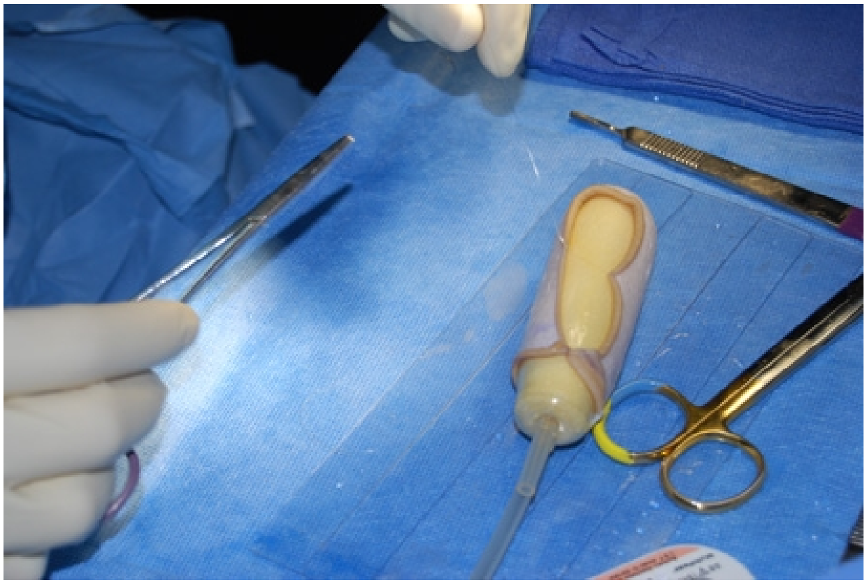
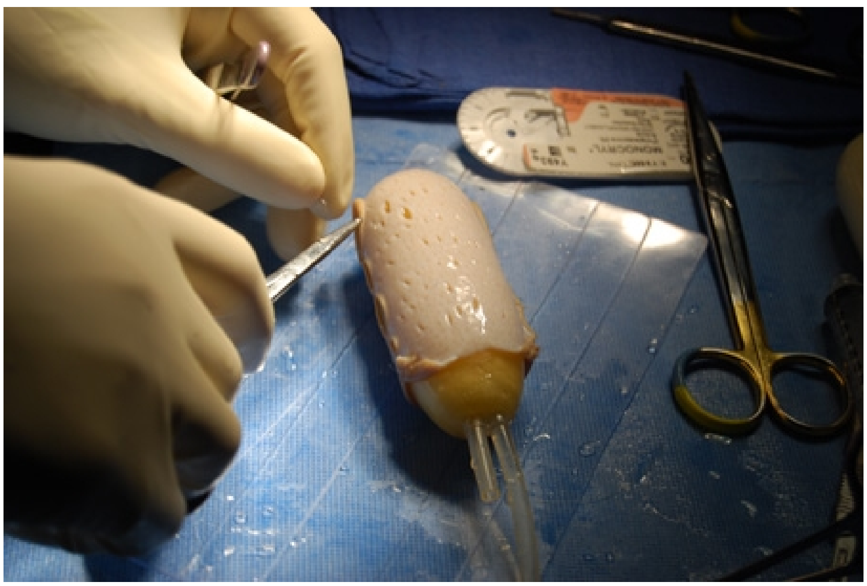
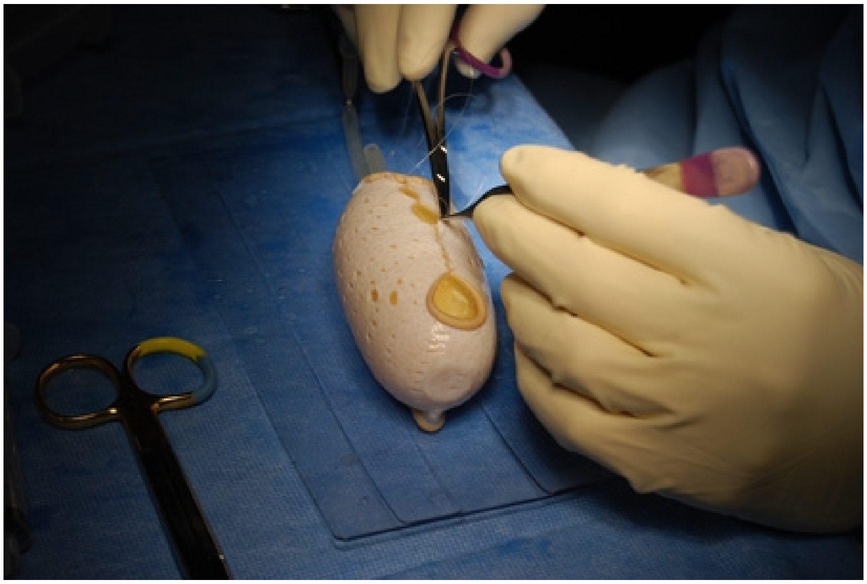
The lateral edges of the skin graft are then approximated on either side of the mold using interrupted sutures.



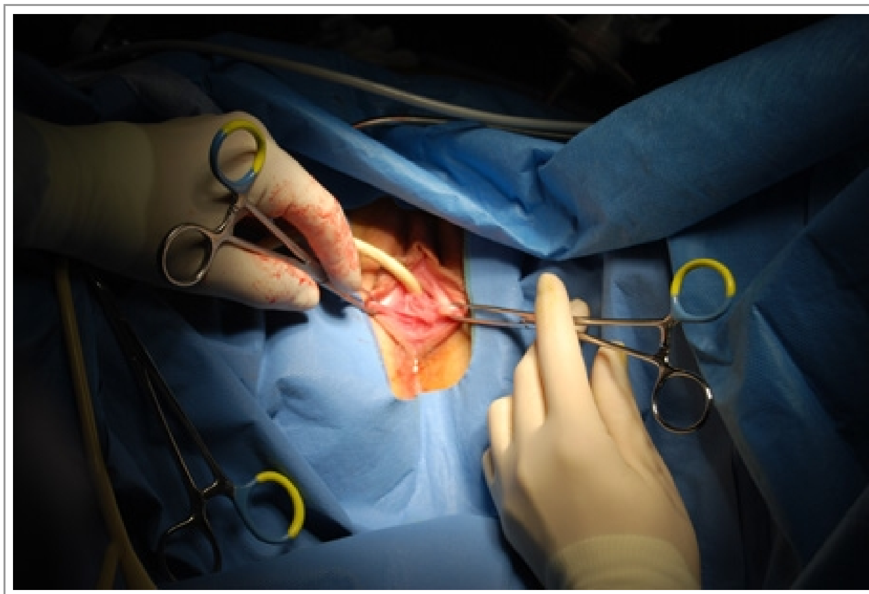
Continued suturing.



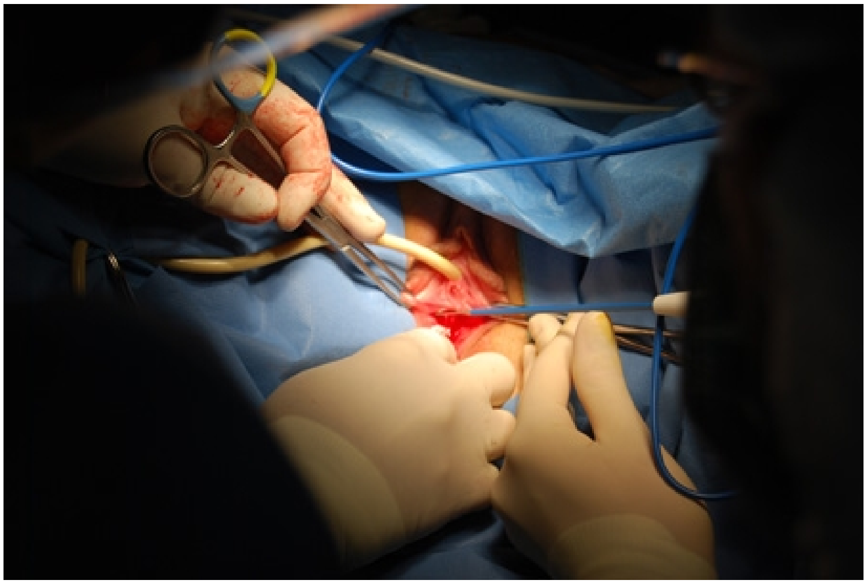


Graft sutured in place around the soft mold.

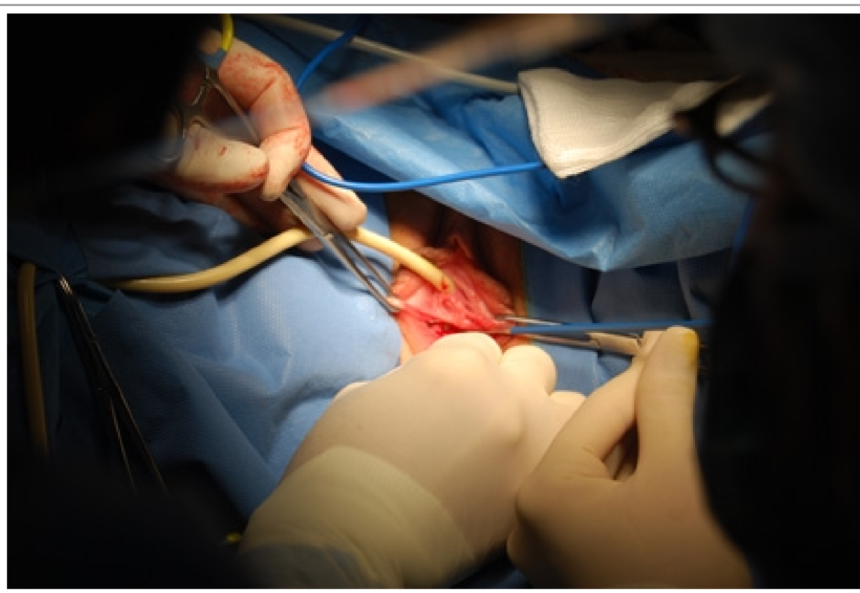
Concurrently with creation of the vaginal mold, the patient is placed in dorsal lithotomy position. Perineal cleansing is performed, and a Foley catheter placed. A dimple in the vestibule is typically identified below the urethra.



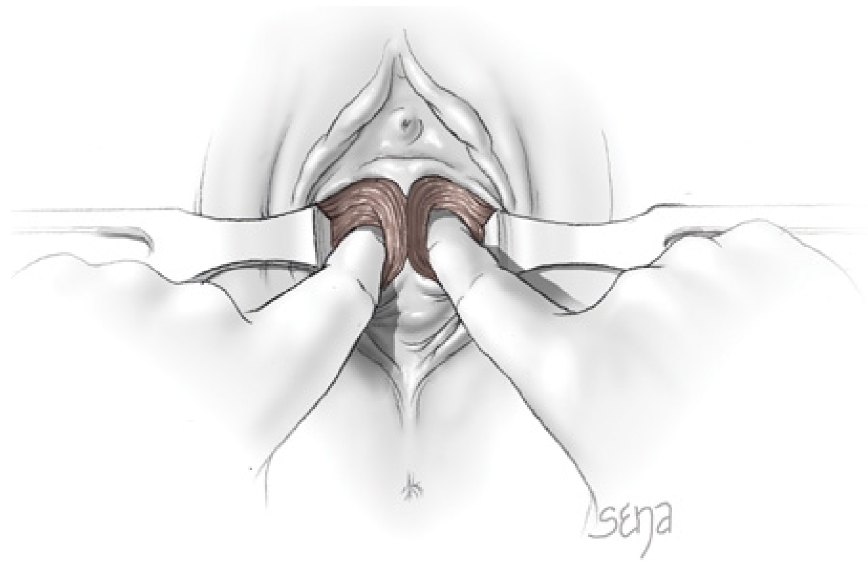
The lower edge of each labia minora is grasped with Allis clamps and extended laterally.



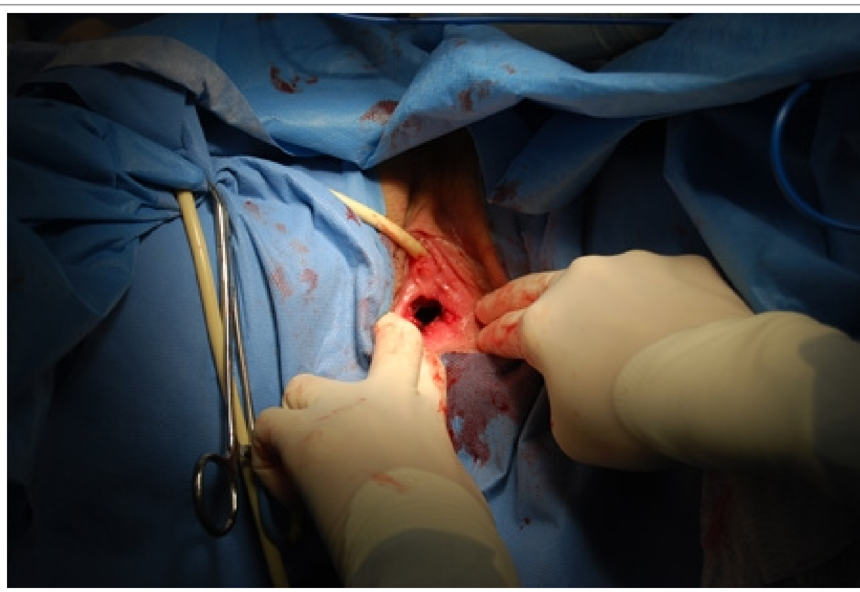
A 2 to 3 cm transverse incision is sharply made across it the dimple. In creation of the new vagina, the goal is to create a canal that is bounded anteriorly by the fascia that supports the urethra and bladder. Posterior limits involve the perirectal fascia and rectum. Lateral borders are the puborectalis muscles. Vaginal depth approximates 12 cm, but entering the cul-de-sac of Douglas peritoneum should be avoided. Thus, the canal is extended to within 2 cm of the cul-de-sac of Douglas. This leaves a layer of connective tissue affixed to the peritoneum. First, the skin graft will attach more effectively to this connective tissue than to the smooth peritoneal surface. Secondly, rates of subsequent enterocoele formation are lowered.



During dissection, several points are noteworthy. First, with initial caudal dissection, the surgeon may meet greater resistance than with the tissues more cephalad. Additionally during dissection, a finger may be placed by the surgeon into the rectum to identify its location and avert perforation. Similarly, the Foley catheter may serve as an orientation tool anteriorly.

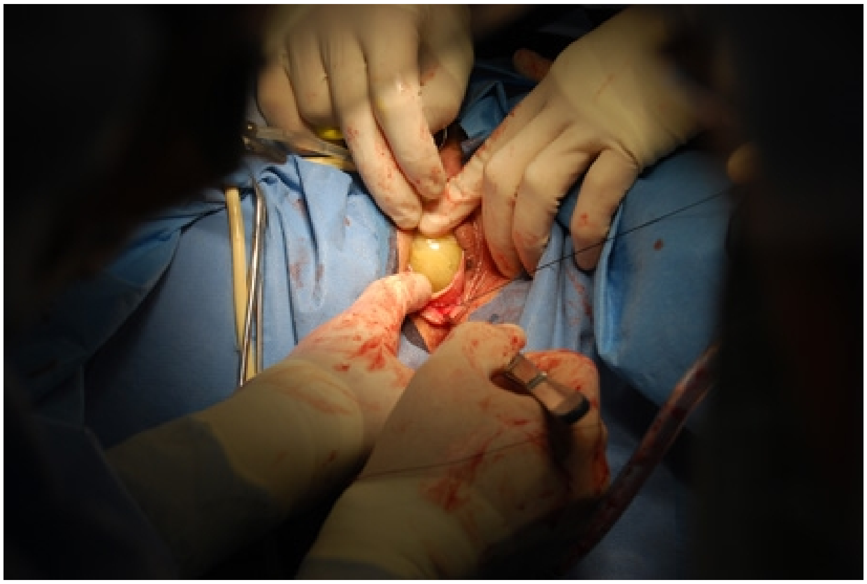


Following the initial incision, two canals are created on either side of the median raphe, which is a midline collection of dense connective tissue bands that stretch between the urethra and bladder above and the rectum below. These canals are initially formed using a spreading motion with blunt-tipped scissors. Fingers are then insinuated into the forming canals. Pressure is exerted cephalad to extend the canal depth. Additionally, the finger pads are rolled outward and lateral pressure is applied to widen the canal. Posterior pressure should be avoided to prevent entering the rectum.

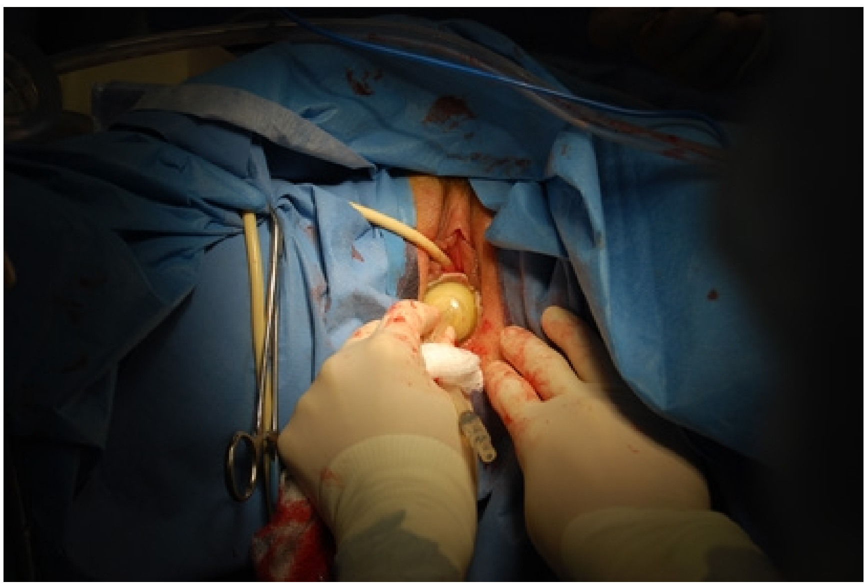


Upon completion of the two smaller canals, the median raphe is cut. The final single canal measures approximately 10 to 12 cm deep and 3 fingerbreadths wide.

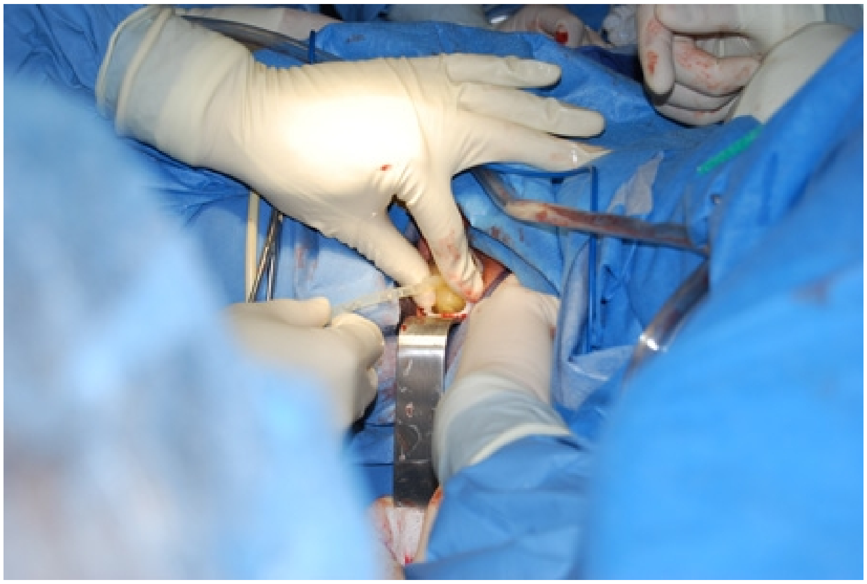
Collections of blood can separate the mold from the canal bed, thus hemostasis is required prior to mold insertion.



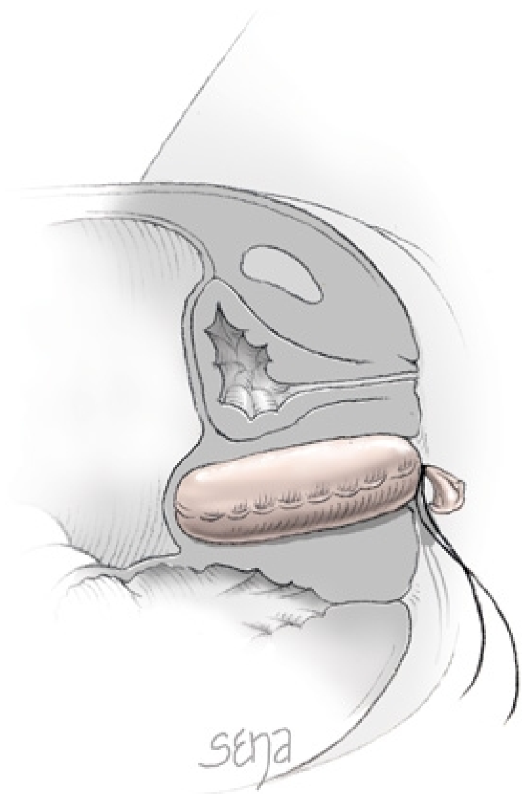
Once appropriately sized and constructed, the mold is then inserted.



Customizing the mold to the size of the created neovaginal canal is essential. If a mold width is too large, it can cause pressure necrosis or inhibit adequate drainage, which as noted earlier can lead to tissue maceration. Moreover, at the time of postoperative mold removal a mold which is too large and snuggly fitted into the neovagina may pull loose the graft.



Soft mold and graft in place.



Lateral image depicting the soft mold in place.

Edges of the skin graft at the distal end of the mold are then reapproximated to the distal opening of the neovagina using 4- or 5-0 delayed absorbable suture. The labia minora, if sufficiently long, can be sutured together along the midline with 2-0 silk sutures to help hold the mold in place for the first 7 postoperative days. An elastic compression dressing is placed on the perineum.

MEDICAL HISTORY AND PHYSICAL EXAMINATION

For many women, gynecologists often serve as both specialist and primary care provider, and as such, are given an opportunity to prevent and treat a wide variety of diseases. The incidence of these may vary greatly depending on the age group treated. Thus, the focus of medical questioning should reflect these changing risks.

Following historical inventory, a complete physical examination is completed (American College of Obstetricians and Gynecologists, 2003c). Many women present to their gynecologists with complaints specific to the breast, vulva, or vagina. Accordingly, these are often areas of increased focus, and their evaluation is described below.

Breast Examination

Although mammography has been shown to effectively detect breast cancers, clinical breast examination (CBE) may identify a small portion of these malignancies not detected with mammography. Additionally, CBE may identify cancer in young women, who are not typical candidates for mammography (McDonald, 2004). Clinical breast examination can be completed with various methods. However, in an attempt to standardize performance, a committee for the American Cancer Society has described a CBE that combines visual inspection with axillary and breast palpation (Saslow, 2004).

BREAST INSPECTION

Initially, the breasts should be viewed as a woman sits on the table's edge with her hands pushing against her hips to flex the pectoralis muscles. Alone, this position enhances asymmetry, and additional arm positions, such as placing arms above the head, are not required to add vital information. Breast skin is inspected for erythema; retraction; scaling, especially over the nipple; and edema, termed *peau d'orange* change. Additionally, the breasts and axillae are observed for contour symmetry.

LYMPH NODE EVALUATION

Following inspection, axillary, supraclavicular, and infraclavicular lymph nodes are palpated most easily with a woman seated and her arm resting at her side but supported by the examiner. The axilla is bounded by the pectoralis major muscle ventrally and the latissimus dorsi muscle dorsally. Lymph nodes are detected as the examiner's hand glides from high to low in the axilla and momentarily compresses nodes against the lateral chest wall. In a thin patient, one or more mobile lymph nodes measuring <1 cm in diameter are commonly appreciated. The first lymph node to become involved with breast cancer metastases (the sentinel node) is nearly always located just behind the midportion of the pectoralis major muscle.

BREAST PALPATION

After inspection, breast palpation is completed with a woman supine and with one hand above her head to stretch breast tissue across the chest wall (Fig. 1-1). Examination should include breast tissue bounded by the clavicle, sternal border, inframammary crease, and midaxillary line. Breast palpation within this bounded area is approached in a linear fashion. The technique should use the finger pads in a continuous rolling, gliding circular motion (Fig. 1-2). At each palpation point, tissues should be assessed both superficially and deeply (Fig. 1-3). During CBE, intentional attempts at nipple discharge expression are not required unless a *spontaneous* discharge has been described by the patient.

If abnormal breast findings are noted, they are described by their location in the right or left breast, clock position, distance from the areola, and size. Evaluation and treatment of breast and nipple diseases are described more fully in Chapter 12.

Pelvic Examination

This examination is typically performed with a patient supine, legs in dorsal lithotomy position, and feet resting in stirrups. The head of the bed is elevated 30Â° to relax abdominal wall muscles for bimanual examination. A woman should be assured that she may stop or pause the examination at any time. Moreover, each part of the evaluation should be announced or described before its performance.

INGUINAL LYMPH NODES AND PERINEAL INSPECTION

Pelvic cancers and infections may drain to the inguinal lymph nodes, and these should be palpated during examination. Following this, a methodical inspection of the perineum should extend from the mons ventrally, to the genitocrural folds laterally, and to the anus. Infections and neoplasms that involve the vulva may also involve perianal skin, and this area should be similarly inspected. Some clinicians also palpate for Bartholin and paraurethral gland pathology. However, in most cases, patient symptoms and asymmetry in these areas will dictate the need for their evaluation.

SPECULUM EXAMINATION

The vagina and cervix are typically viewed after placement of either a Graves or Pederson speculum (Fig. 1-4). Within these two general classes of speculums, various sizes are available to accommodate vaginal length and laxity. Prior to insertion, a speculum may be warmed. Additionally, lubrication may add comfort to insertion. Griffith and colleagues (2005) found that water-based gel lubricants, placed on the outer speculum bill, did not increase unsatisfactory conventional Pap smear cytology or decrease Chlamydia trachomatis detection rates compared with water lubrication.

FIGURE 1-4

Photograph displays Pederson **(A)** and Graves **(B)** vaginal speculums. *(Courtesy of Dave Gresham.)*

Prior to insertion, the labia minora are gently separated, and the urethra is identified. Because of urethral sensitivity, the speculum is inserted below the meatus. Alternatively, prior to speculum placement, an index finger may be placed in the vagina and pressure placed against the bulbocavernosus muscle. A woman is then encouraged to relax this posterior wall muscle to improve comfort with speculum insertion. This practice may prove especially helpful for women undergoing their first examination, those with infrequent coitus, or those with heightened anxiety.

With speculum insertion, the vagina commonly contracts, and a woman may note pressure or discomfort. A pause at this point typically is followed by vaginal muscle relaxation. As the speculum bill is completely inserted, it is angled 30Â° downward to reach most cervices. Commonly, the uterus lies in an anteverted position, and the face of the cervix lies against the posterior vaginal wall (Fig. 1-5).

FIGURE 1-5

Image depicting an anteverted uterus. Note that the ectocervix faces the posterior vaginal wall. *(From Reiffenstuhl and Platzer, 1975, with permission.)*

As the speculum is opened, the ectocervix can be identified. Vaginal walls and cervix should be inspected for masses, ulceration, or unusual discharge. As outlined in Chapter 29, Performing a Pap Test, a Pap smear is obtained and additional swabs for culture or microscopic evaluation may also be collected (see Chap. 3, Diagnosis).

BIMANUAL EXAMINATION

Uterine and adnexal size, mobility, and tenderness can be assessed during bimanual examination. For women with prior hysterectomy and adnexectomy, bimanual examination is still valuable and can be used to exclude other pelvic pathology.

During this examination, a gloved index and middle finger are inserted together into the vagina until the cervix is reached. To ease insertion, a water-based lubricant may be initially applied to these fingers. Once the cervix is reached, uterine orientation can be quickly assessed by sweeping the index finger inward along the anterior surface of the cervix. In those with an anteverted position, the uterine isthmus is noted to sweep upward, whereas in those with a retroverted position, a soft bladder is palpated. However, in those with a retroverted uterus, if a finger is swept along the cervix's posterior surface, the isthmus is felt to sweep downward. With a retroverted uterus, this same finger is continued posteriorly to the fundus and then side-to-side to assess uterine size and tenderness.

To determine the size of an anteverted uterus, fingers are placed beneath the cervix, and upward pressure tilts the fundus toward the anterior abdominal wall. A clinician's opposite hand is placed against the abdominal wall to locate the upward fundal pressure (Fig. 1-6).

FIGURE 1-6

To assess adnexa, clinicians use their two vaginal fingers to lift adnexa from the cul-de-sac toward the anterior abdominal wall. An adnexum is trapped between these vaginal fingers and the clinician's other hand, which is exerting downward pressure against the lower abdomen. For those with normal-sized uteri, this abdominal hand is typically best placed just above each inguinal ligament and pubic rami.

RECTOVAGINAL EXAMINATION

The decision to perform a rectovaginal examination varies among providers. Although some prefer to complete this evaluation on all adults, others elect to perform rectovaginal examination for those with specific indications such as pelvic pain, an identified pelvic mass, rectal symptoms, or need for colon cancer screening.

Gloves may be changed between bimanual and rectovaginal examinations to avoid contamination of the rectum with potential vaginal pathogens. Initially, an index finger is placed into the vagina and a middle finger into the rectum. These fingers are swept horizontally against one another in a scissoring fashion to assess the rectovaginal septum for scarring or peritoneal studding (Fig. 1-7). The index finger is removed, and the middle finger completes a circular sweep of the rectal vault to exclude masses. If immediate guaiac testing is indicated, it may be performed with a sample from this portion of the examination.

PREVENTIVE CARE

As primary care providers, gynecologists have an opportunity to prevent leading causes of female morbidity and mortality. Accordingly, a familiarity with screening and general treatment guidelines is essential.

Infection Prevention

VACCINATION

Although many vaccines are recommended routinely for most adults, others may be warranted less frequently and are indicated because of co-morbid patient risks. Recommendations for adult vaccination are summarized in Table 1-1, and a complete discussion of specific as well as general guidelines can be found at the Centers for Disease Control and Prevention (CDC) website: http://www.cdc.gov/vaccines/recs/schedules/downloads/adult/06-07/adult-schedule.pdf .

Table 1-1 Summary of Recommendations for Adult Immunization

Vaccine Name and Route	**Reason to Vaccinate**	**Vaccine Administration (any vaccine can be given with another)**	**Contraindications and Precautions[a] (mild illness is not a contraindication)**
Influenza Trivalent inactivated influenza vaccine (TIV) *Give IM*	■ Persons aged 50 yrs and older ■ Persons with serious medical problems such as heart disease, diabetes, renal dysfunction, and conditions that compromise respiratory function	■ October and November are ideal months to give TIV ■ LAIV may be given as early as August	**Precaution** ■ History of Guillain-BarrÃ© syndrome within 6 wks previous TIV

	respiratory function. ■ Women who will be pregnant during the influenza season (December-March) ■ Persons working or living with at-risk people ■ Household contacts or caregivers of children 0-59 mos ■ Travelers to at-risk areas. ■ Students or other persons in institutional settings ■ Anyone wishing to reduce the risk of influenza	■ May continue to give TIV and LAIV from December through March	
Influenza Live attenuated influenza vaccine (LAIV) *Give intranasally*	■ Healthy, nonpregnant persons aged 49 yrs and younger who meet any of the last 5 conditions for TIV	■ October and November are ideal months to give TIV ■ LAIV may be given as early as August ■ May continue to give TIV and LAIV from December through March	**Contraindication** ■ As above, plus pregnancy or serious chronic medical disorders
Pneumococcal polysaccharide (PPV) *Give IM or SC*	■ Persons aged 65 yrs and older ■ Persons who have chronic illness, asplenia, or immunosuppression	■ Routinely given as a onetime dose; administer if previous vaccination history is unknown ■ One-time revaccination is recommended 5 yrs later for persons at highest risk and for persons age 65 yrs and older if the 1st dose was given prior to age 65 and 5 yrs have elapsed since the previous dose	
Hepatitis B (Hep B) *Give IM*	■ All adolescents; any adult wishing to obtain immunity. ■ High-risk persons, including household contacts and partners of HBsAg-positive persons; injecting drug users; heterosexuals with more than one	■ Three doses are needed on a 0-, 1-, 6-mo schedule ■ Alternative timing options for vaccination include 0, 2, 4 mos and 0, 1, 4 mos. If the	

	sex partner; MSM; persons with STDs; patients receiving hemodialysis; recipients of certain blood products; health care workers, and certain international travelers. ▪ Persons with chronic liver disease	series is delayed between doses, do not restart series, but complete it ▪ For the hepatitis A and B combination vaccine, three doses are needed on a 0-, 1-, 6-mo schedule. Recipients must be 18 yrs or older	
Hepatitis A (Hep A) *Give IM*	▪ Persons who travel or work anywhere except the U.S., Western Europe, New Zealand, Australia, Canada, and Japan ▪ Persons with chronic liver disease; drug users; MSM; people with clotting-factor disorders; and food handlers when health authorities or private employers determine vaccination to be cost effective ▪ Anyone wishing to obtain immunity to hepatitis A	▪ Two doses are needed. ▪ The minimum interval between doses #1 and #2 is 6 mos	**Precaution** ▪ Safety during pregnancy has not been determined, so benefits should be weighed against potential risk
Td, Tdap (Tetanus, diphtheria, pertussis) *Give IM*	▪ All adults who lack a history of primary series consisting of at least three doses of tetanus-and diphtheria-containing vaccine ▪ A booster dose of tetanus- and diphtheria-containing toxoid may be needed for wound management as early as 5 yrs after receiving a previous dose *For Tdap (tetanus- and diphtheria-toxoids with acellular pertussis vaccine) only:* ▪ All adults aged younger than 65 yrs who have not received Tdap	▪ For persons who are unvaccinated, complete the primary series with Td (spaced at 0, 1- to 2-mo, and 6- to 12-mo intervals). One dose of Tdap may be used for any dose if aged 19-64 yrs ▪ Give Td booster every 10 yrs after the primary series has been completed. For adults aged 19-64 yrs, a 1-time dose of Tdap is recommended to replace the text Td	**Contraindication** ▪ For Tdap only, history of encephalopathy within 7 days following DTP/DTaP **Precaution** ▪ Guillain-BarrÃ© syndrome within 6 wks of receiving a previous dose of tetanus toxoid-containing vaccine ▪ Unstable neurologic condition **Note** : Use of Td or Tdap is not contraindicated in pregnancy. At the provider's discretion, either vaccine may be administered during the second or third trimester
Varicella (Var) (Chickenpox) *Give SC*	▪ All adults without evidence of immunity, which is defined as a history of vaccination, previously	▪ Two doses are needed on a 0 and 1- or 2-mo schedule. If the second	**Contraindications** ▪ Pregnancy or possibility of pregnancy within 4 wks

	diagnosed varicella disease, or laboratory evidence of immunity	dose is delayed, do not repeat dose #1; just give dose #2	■ Immunocompromised persons
Meningococcal Conjugate vaccine (MCV4) *Give IM* Polysaccharide vaccine (MPSV4) *Give SC*	■ College freshmen living in dormitories ■ Anatomic or function asplenia or terminal complement component deficiencies ■ Travel to or residence in countries in which meningococcal disease is hyperendemic or epidemic	■ One dose is needed ■ If previous vaccine was MPSV4, revaccinate after 5 yrs if risk continues ■ Revaccination after MCV4 is not recommended	**Precaution** ■ For MCV4 only, history of Guillain- BarrÃ© syndrome
MMR (Measles, mumps, rubella) *Give SC*	■ Persons born in 1957 or later should receive at least one dose of MMR if there is no serologic proof of immunity ■ Women of childbearing age who do not have acceptable evidence of rubella immunity or vaccination	■ One or two doses are needed ■ If a pregnant woman is found to be rubella susceptible, administer MMR postpartum	**Contraindications** ■ Pregnancy or possibility of pregnancy within 4 wks **Precaution** ■ Severe immunosuppression ■ History of thrombocytopenia or thrombocytopenia purpura
Human papillomavirus (HPV) *Give IM*	■ All previously unvaccinated women through age 26 yrs	■ Three doses are needed on a 0, 1- to 2- , and 6-mo schedule	**Precaution** ■ Data on vaccination in pregnancy are limited; therefore, vaccination should be delayed until postpartum

[a] Previous anaphylactic reaction to any of a vaccine's components serves as a contraindication for any vaccine. Moderate to severe illness is a precaution to vaccination.

DTP = diphtheria, tetanus, pertussis vaccine; HBSAg = hepatitis B surface antigen; MSM = men having sex with men; STD = sexually transmitted disease.

SEXUALLY TRANSMITTED DISEASE SCREENING

Routine screening for sexually transmitted disease is not warranted for all women. However, certain testing is recommended for selected groups to decrease morbidity and disease transmission (Table 1-2). These and other infections of the reproductive tract are discussed in Chapter 3.

Table 1-2 Sexually Transmitted Disease Screening Guidelines for Nonpregnant, Sexually Active Asymptomatic Women		
Infectious Agent	**Recommendations**	**Risk Factors**
Chlamydia trachomatis + *Neisseria gonorrhoeae*	Screen all ≤25 years. Screen those older if risk factors present	New or multiple partners; inconsistent condom use; sex work; concurrent STD, prior chlamydial infection or gonorrhea
Treponema pallidum	Should screen those with risk factors	Sex work; confinement in adult correction facility; MSM
HIV virus	Should screen those with risk factors	Multiple partners; injection drug use; sex work; concurrent STD; MSM; transfusion between 1978 and 1985
Hepatitis C virus	May screen those with risk factors	Injection drug use; dialysis; partner with hepatitis C; multiple partners; received blood products prior to 1990
Hepatitis B virus	No routine screening	
Herpes simplex virus 2	No routine screening	

HIV = human immunodeficiency virus; MSM = men having sex with men; STD = sexually transmitted disease.

Contraception

For reproductive-aged women, contraceptive needs or plans for pregnancy should be discussed annually. Contraceptive counseling is covered in Chapter 5 but generally should include education on methods, their use, efficacy, side effects, noncontraceptive benefits, and contraindications. However, despite efforts to provide contraception, nearly half of all pregnancies are unintended. Accordingly, a discussion of emergency contraceptive methods is warranted. Additionally, all reproductive-aged women are encouraged to take a 400-μg folic acid supplement daily to prevent fetal neural-tube defects (NTDs) if pregnancy occurs. Women at higher risk for fetuses with NTD should supplement with 4 mg orally each day (American College of Obstetricians and Gynecologists, 2003b).

Alternatively, for those desiring pregnancy, topics found in Table 1-3 should be addressed to maximize maternal and fetal health (American College of Obstetricians and Gynecologists, 2005).

Table 1-3 Preconception Topics	
Action	**Risk Reduction**
Review contraceptive use	Prevent unintended pregnancy
Advise smoking cessation or at minimum, decreased smoking	Decrease risk of pregnancy loss Increase birthweight Decrease risk of sudden infant death syndrome
Advise abstinence from alcohol or at minimum, decreased consumption	Prevent fetal alcohol syndrome
Supplement with folic acid	Decrease risk of neuralâ€"tube defects
Screen for HIV infection	Decrease perinatal transmission by giving antiretroviral treatment Avoid transmission via breast milk
Screen for hepatitis B virus	Protect neonate from infection by administering vaccine antepartum
Screen for other sexually transmissible infections	Protect maternal fertility Prevent fetal and neonatal infection
Immunize	Prevent vaccine-preventable diseases
Control diabetes	Decrease risk of congenital anomaliesxs
Screen for genetic diseases	Provide choices about pregnancy outcome
Counsel about domestic violence	Prevent injuries
Review psychosocial status	Improve emotional support and well-being

HIV = human immunodeficiency virus.

Cancer Screening

For women having periodic health examinations, screening for certain cancers may be indicated for early detection.

CERVICAL CANCER

This cancer is common and is preventable in many cases with routine Pap smear screening. A detailed discussion of Pap smear collection technique and guidelines is presented in Chapter 29, Performing a Pap Test, but a brief overview is provided here.

In general, women should begin Pap smear screening within 3 years after beginning vaginal intercourse and no later than age 21. Subsequently, regular Pap test collection should follow every year or every 2 years using newer liquid-based Pap tests (American College of Obstetricians and Gynecologists, 2003a; Saslow, 2002). In those older than 30, if three normal test results are obtained, then screening may be spaced at 2- to 3-year intervals. However, co-morbid risks for cervical cancer such as diethylstilbestrol (DES) exposure and immunosuppression may warrant annual screening even in this age group (see Chap. 29, Screening Recommendations) (Smith, 2006).

In contrast, screening may be discontinued for selected groups. For example, women aged 70 years or older who have had three consecutive normal Pap test results, no history of preinvasive lesions, and no co-morbid risks for cervical cancer may elect to halt screening. In addition, following hysterectomy, women without a history of invasive or preinvasive cervical disease may also choose to stop cytologic screening (U.S. Preventive Services Task Force, 2003a).

ENDOMETRIAL CANCER

Some women with multiple family members with colon cancer may have hereditary nonpolyposis colon cancer (HNPCC), as defined in Chapter 33. For women with HNPCC or those at high risk for this syndrome, annual screening should be offered for endometrial cancer with endometrial biopsy beginning at age 35 (American Cancer Society, 2006b).

For most other asymptomatic women, routine endometrial cancer screening is not recommended. However, clinicians should educate women, especially those with risk factors, about this cancer's typical symptoms.

OVARIAN CANCER

Routine screening of asymptomatic women at low risk for ovarian cancer with either cancer antigen 125 (CA125) level measurement or sonography is not recommended. Currently, annual pelvic examination is the primary prevention tool for these women. However, for women who carry BRCA1 or BRCA2 gene mutations or those with a strong family history of breast and ovarian cancer, these two screening tools may be offered. A complete discussion of ovarian cancer screening can be found in Chapter 35, Genetic Screening.

BREAST CANCER

Guidelines from the American Cancer Society were published in 2003 (Table 1-4). Based on trials showing decreased mortality in women 40 years and older who were screened with mammography, mammograms are recommended starting at age 40 for those with average risk and may be continued yearly (Smith, 2003). For those with greater risk, early or more frequent screening or the addition of other imaging tools may be warranted. A fuller discussion of breast cancer and screening can be found in Chapter 12, Breast Cancer Screening.

Table 1-4 American Cancer Society Guidelines for Early Breast Cancer Detection

Women at Average Risk	Begin mammography at age 40.
	For women in their 20s and 30s, it is recommended that CBE be part of a periodic health examination, preferably at least every 3 years. Asymptomatic women aged 40 and older should continue to receive CBE as part of a periodic health examination, preferably annually.
	Beginning in their 20s, women should be told about the benefits and limitations of BSE. Women who choose to do BSE should receive instruction at their periodic health examination. It is acceptable for women to choose not to do BSE or to do BSE irregularly.
Older Women	Screening decisions in older women should be individualized in the context of current health status. As long as a woman would be a candidate for treatment, she should continue to be screened with mammography.
Women at Increased Risk	Women at increased risk of breast cancer might benefit from additional screening strategies. These may include earlier initiation of screening, shorter screening intervals, or the addition of screening modalities such as ultrasonography or magnetic resonance imaging.

BSE = breast self-examination; CBE = clinical breast examination.

COLON CANCER

Several organizations recommend screening patients at average risk for colorectal cancer beginning at age 50 with any of the five

methods shown in Table 1-5. Prior to fecal occult blood testing (FOBT), women should avoid nonsteroidal anti-inflammatory drugs (NSAIDs) 7 days prior to testing. Additionally, vitamin C, red meats, raw cauliflower, broccoli, members of the radish family, and melons should be avoided for 3 days before testing. Positive tests warrant further evaluation with colonoscopy.

Table 1-5 Summary of Recommendations for Colorectal Cancer Screening in Average-Risk Patients[a]

	U.S. Preventive Services Task Force	**American College of Gastroenterology**	**American Cancer Society**
FOBT	Good evidence for periodic testing	Annual	Annual
FS	Fair evidence for periodic testing	Every 5 years	Every 5 years
FS + FOBT	Fair evidence for periodic testing	Annual, every 5 years, respectively	Annual, every 5 years, respectively
Colonoscopy	No direct evidence of CRC mortality reduction; indirect evidence supports its use	Every 10 years	Every 10 years
DCBE	No direct evidence of CRC mortality reduction	Every 5 years	Every 5 years

[a] Screening begins at age 50 for those at average risk.

CRC = colorectal cancer; DCBE = double-contrast barium enema; FOBT = fecal occult blood testing; FS = flexible sigmoidoscopy.

Modified from Huang, 2005, with permission.

Although these guidelines are appropriate for those with average risk, individuals with a personal or family history of colon cancer, chronic inflammatory bowel disease, prior polyps, or other high-risk factors should be screened more frequently (American Cancer Society, 2006a).

Osteoporosis

In the United States, approximately 15 percent of women older than 50 years have osteoporosis, and 35 to 50 percent have osteopenia (Ettinger, 2003). These bone-weakening conditions lead to increased rates of fracture, and bone mass density has been shown to correlate inversely with risks for these fractures. Accordingly, tools that measure bone density such as dual-energy x-ray absorptiometry (DEXA) scanning are used to identify bone loss and predict fracture risk (see Chap. 21, Diagnosis of Osteoporosis). Screening guidelines from the National Osteoporosis Foundation (2003) as to the appropriate use of such radiologic tools is listed in Table 1-6.

Table 1-6 General Guidelines for Prevention and Treatment of Osteoporosis
Counsel all women on the risk of osteoporosis and related fractures.
Advise all women to consume adequate amounts of calcium (at least 1,200 mg/d, including supplements if necessary) and vitamin D (400 to 800 IU/d for those at risk of deficiency).
Recommend regular weight-bearing and muscle-strengthening exercise.
Advise women to avoid smoking and excessive alcohol intake.
Recommend BMD testing to all women aged 65 yrs and older.
Recommend BMD testing to younger postmenopausal women who have one or more risk factors (other than being white, postmenopausal, and female) (See Table 21-6).
Recommend BMD testing to women who have suffered a fragility fracture.
Initiate therapy to reduce fracture risk in postmenopausal women with BMD T-scores by central dual-energy x-ray absorptiometry (DEXA) below â€“2 in the absence of risk factors and in women with T-scores below â€“1.5 if one or more risk factors is present.
Consider postmenopausal women with vertebral or hip fractures candidates for osteoporosis treatment.
Current pharmacologic options for osteoporosis prevention and/or treatment are bisphosphonates (alendronate and risedronate), calcitonin, estrogens and/or hormone therapy, parathyroid hormone, and raloxifene.

BMD = bone mineral density.

Obesity

DIAGNOSIS AND RISKS

In 2003, 62 percent of women in the U.S. were considered overweight or obese (Ogden, 2006). *Overweight* is defined as a body mass index (BMI) ranging from 25 to 29.9 kg/m^2 , whereas *obesity* describes individuals with BMIs, greater than 30 kg/m^2 . *Normal weight* falls within BMIs of 18.5 and 24.9 (Table 1-7). In addition to BMI, waist circumference positively correlates with abdominal fat content, which if increased, can serve as a separate co-morbid risk. For women, waist circumferences greater than 88 cm (35 inches) are considered increased (National Heart, Lung, and Blood Institute, 2000). Circumference is measured at the level of the iliac crests at the end of normal expiration. The measuring tape should be snug but not indent the skin.

In addition to the social stigma that often accompanies increased body weight, overweight and obese women are at increased risk for developing hypertension, hypercholesterolemia, type 2 diabetes mellitus, gallbladder disease, knee osteoarthritis, sleep apnea, coronary heart disease (CHD), and certain cancers (Must, 1999; National Task Force on the Prevention and Treatment of Obesity, 2000). Accordingly, treatment of these women is often directed toward weight loss as well as management of other co-morbid risk factors (Table 1-8).

TREATMENT

Lifestyle Changes

As seen in Fig. 1-8, for overweight women, if two or more risks are present or if an increased waist circumference is present, then management should focus on moderate weight loss through diet and exercise. For obese women, more substantial weight loss over a prolonged period should be promoted with an initial goal of a 10-percent weight loss over 6 months. A detailed discussion of dietary weight loss extends beyond this chapter's scope, but several clinician and patient aids can be found at: http://www.nhlbi.nih.gov/guidelines/obesity/prctgd_c.pdf .

Algorithm for the diagnosis and management of overweight and obese individuals. *(From National Heart, Lung, Blood Institute, 2000.)*

In general, a 10-percent loss within 6 months can be reached in those with BMIs from 27 to 35 with a daily 300- to 500-kcal intake reduction. In those with higher BMIs, a similar loss can be achieved following a 500- to 1,000-kcal reduction.

Medications

In addition to diet and exercise, pharmacologic or surgical options may be implemented for selected obese patients. Sibutramine (Meridia, Abbott Laboratories, North Chicago, IL) is a centrally acting monoamine-reuptake inhibitor that primarily acts as an appetite suppressant (McNeely, 1998). Orlistat (Xenical, Roche Pharmaceutical, Nutley, NJ) is the other Food and Drug Administration (FDA)-approved agent for obesity. A reversible inhibitor of gastric and pancreatic lipases, orlistat leads to a 30-percent blockage of dietary fat absorption (Henness, 2006). The newest weight loss drug, approved in Europe and under consideration in the U.S. is rimonabant, the first cannabinoid (CB_1) antagonist. Receptors of the endocannabinoid system are extensively expressed in the brain, including areas vital to the control of food intake. Rimonabant acts as an appetite suppressant (Padwal, 2007).

Bariatric Surgery

As another adjunct to diet and exercise, bariatric surgery may be selected for those with BMIs ≥ 40 or with BMIs ≥ 35 if other co-morbid conditions are present (Buchwald, 2005). Of available procedures, gastric banding and Roux-en-Y gastric bypass are the most commonly performed (Brethauer, 2006). Both surgeries lead to substantial weight loss in individuals with morbid obesity and have been linked with improved co-morbid risk factors and decreased mortality rates (Christou, 2004; Sjostrom, 2004). However, surgical complications can be serious and include pulmonary embolism, gastrointestinal leaks in staple or suture lines, stomal obstruction or stenosis, and bleeding (Steinbrook, 2004).

Chronic Hypertension

Chronic hypertension is common and an estimated 39 million American women are hypertensive (American Heart Association, 2005). The risk of hypertension increases with age, and more than 65 percent of those older than 60 have elevated blood pressures (Ong, 2007; Vasan, 2002). Hypertension is a significant health concern and increases risks of myocardial infarction, stroke, congestive heart failure, renal disease, and peripheral vascular disease. To minimize these effects, gynecologists should be familiar with criteria used to diagnose hypertension. Although many may choose to refer their patients for treatment of hypertension, gynecologists should be aware of target goals and long-term risks associated with this disease.

DIAGNOSIS

Physical Examination

Blood pressures should ideally be taken with a woman seated in a chair with the tested arm resting on a table. An appropriately sized cuff is selected, and the cuff bladder should be large enough to encircle at least 80 percent of the arm. Hypertension is diagnosed if readings are elevated on at least two separate office visits.

As seen in Table 1-9, a new category of hypertension was introduced in 2003 by the Seventh Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (National Heart, Lung, and Blood Institute, 2003). *Prehypertension* is diagnosed if readings range from 130-139/80-89 mm Hg. This range is important, as women with prehypertension are at significantly increased risk of developing hypertension later (Wang, 2004). Additionally, compared with normal blood pressure readings, prehypertension is associated with greater risks for cardiovascular disease (CVD) (Mainous, 2004).

Table 1-9 Classification and Treatment of Hypertension

Classification	**SBP (mm Hg)**		**DBP (mm Hg)**	**No Compelling Indication[a]**	**Those with a Compelling Indication[a]**
Normal	<120	**and**	<80	No antihypertensive drug	No antihypertensive drug
Prehypertension	120â€“139	**or**	80â€“90	No antihypertensive drug	Drugs for the compelling indication(s).
Stage 1 hypertension	140â€“159	**or**	90â€“99	Thiazide-type diuretics for most. May consider ACEIs, ARBs, BBs, CCBs, or combination	Drugs for the compelling indication(s). ACEIs, ARBs, BBs, CCBs as needed
Stage 2 hypertension	≧ 160	**or**	≧ 100	Two-drug combination for most, usually thiazide- type diuretic and ACEIs or BB or CCB	Drugs for the compelling indication(s). Add diuretics, ACEIs, ARBs, BBs, CCBs, as needed

ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensinâ€“receptor blocker; BB = β -blocker; CCB = calcium-channel blocker; DBP = diastolic blood pressure; SBP = systolic blood pressure.

[a] Compelling indications include (1) congestive heart failure, (2) myocardial infarction, (3) diabetes, (4) chronic renal failure, (5) prior stroke. Lifestyle modifications are encouraged for all and include (1) weight reduction if overweight, (2) alcohol intake limitation, (3) increased aerobic physical activity (30â€“45 minutes daily), (4) sodium intake reduction (<2.34 g/d), (5) smoking cessation, and (6) Dietary Approaches to Stop Hypertension (DASH) diet (See Table 1â€“11).

From National Heart, Lung, and Blood Institute 2003, with permission.

If hypertension is diagnosed, further examination should exclude underlying causes of hypertension and resultant end-organ disease (Table 1-10). Accordingly, examination should include confirmation of comparable blood pressure in the contralateral arm; optic fundi examination; calculation of BMI and measurement of waist circumference; auscultation for carotid, abdominal, and femoral bruits; thyroid gland palpation; heart and lung auscultation; abdominal examination for renal enlargement and abnormal aortic pulsation; and inspection for edema and pulses.

Laboratory Tests and Other Diagnostic Procedures

Routine laboratory tests recommended before initiating therapy include an electrocardiogram, urinalysis, blood glucose, hematocrit, lipid profile, and serum potassium and creatinine testing. A more extensive search for identifiable causes may not be generally indicated unless hypertension is not controlled with initial treatment (Chobanian, 2003).

TREATMENT

Lifestyle intervention provides an effective means to lower blood pressure and can be used to prevent and treat hypertension (Table 1-11). However, if blood pressure is significantly elevated, resistant to lifestyle changes alone, or if other co-morbid conditions exist, then pharmacologic treatment may be needed to decrease long-term complications. Medications used for treatment are numerous and an extensive listing can be found at: http://www.nhlbi.nih.gov/guidelines/hypertension/express.pdf .

Table 1-11 Management of Prehypertension			
Strategy	**Recommendation**	**Approximate SBP Reduction**	**Effect on Incidence or Prevalence of Hypertension**
DASH dietary pattern	4â€“5 fruits/day 4â€“5 vegetables/day 2â€“3 low-fat diary/day <25% fat	3.5 mm Hg	Decreased by 62% (prevalence)

Diabetes Mellitus

Diabetes is common and approximately 20 million adults in the U.S. are diabetic (National Institute of Diabetes and Digestive and Kidney Disease, 2005). The long-term consequences of this endocrine disorder are serious and include coronary heart disease, stroke, peripheral vascular disease, periodontal disease, nephropathy, neuropathy, and retinopathy.

SCREENING

Currently, the U.S. Preventive Services Task Force (2003b) concludes that there is insufficient evidence to recommend routine screening of asymptomatic adults for type 2 diabetes, unless hyperlipidemia or hypertension is co-existent. However, the American Diabetes Association (2004) recommends that screening be considered at 3-year intervals beginning at age 45, particularly in those with BMIs ≥25. Moreover, testing should be considered at a younger age or completed more often in those who are overweight and have one or more of the other risk factors shown in Table 1-12. Aside from screening, women with overt hyperglycemia symptoms such as polyuria, polydipsia, and blurred vision should undergo diagnostic testing for diabetes.

Diabetes may be diagnosed by different methods, which are shown in Table 1-13. Laboratory measurement of plasma glucose concentration is performed on venous samples, and the diagnostic criteria are based on the use of such methods. Elevated values, in the absence of unequivocal hyperglycemia, must be confirmed on a subsequent day by any of these three methods. In contrast, although hemoglobin A_{1c} measurement and capillary blood glucose testing using a blood glucometer are effective monitoring tools, they are not currently recommended for diagnostic use (American Diabetes Association, 2004).

Table 1-13 Diagnostic Criteria for Diabetes Mellitus
Symptoms of diabetes plus casual plasma glucose concentration ≥200 mg/dL (*casual* is defined as any time of day without regard to time since last meal). The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
or
FPG ≥126 mg/dL. *Fasting* is defined as no caloric intake for at least 8 h.
or
2-h postload glucose ≥200 mg/dL during an OGTT. The test should be performed as described by WHO, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

FPG = fasting plasma glucose; OGTT = oral glucose tolerance test; WHO = World Health Organization.

TREATMENT

Delayed onset and slower progression of many diabetic complications has been shown to follow control of elevated blood glucose

levels (Cleary, 2006; Fioretto, 2006; Martin, 2006). Control can be achieved with diet modification alone or combined with oral hypoglycemic agents or injectable insulin. To lower diabetic morbidity, therapy goals include hemoglobin A_{1c} levels below 7 percent, blood pressure readings below 130/80 mm Hg, low-density lipoprotein (LDL) levels less than 100 mg/dL, weight loss, and smoking cessation (National Diabetes Education Program, 2004).

Cardiovascular Disease

In 2004, nearly 37 percent of the female population was affected by cardiovascular disease and 460,000 women died from its complications (American Heart Association, 2005). Guidelines for prevention encourage surveillance and initial assessment of a woman's risk for cardiovascular disease (CVD) (Mosca, 2004). At its simplest, a woman's risk is calculated by totaling points assigned for smoking, age, lipid levels, and hypertension. An online calculator can be found at: http://hp2010.nhlbihin.net/atpiii/calculator.asp?usertype=prof . Termed the *Framingham 10-year CHD risk score* , point totals are broadly categorized into risk level as: high risk (>20-percent risk of CHD), intermediate (10 to 20 percent 10-year risk), and lower risk (<10 percent risk). Recommendations for prevention of CVD are listed in Table 1-14 and are stratified according to these risk levels.

Metabolic Syndrome

DIAGNOSIS AND PREVALENCE

This syndrome is a clustering of major cardiovascular disease risk factors (Table 1-15). At present, a single unifying cause of the metabolic syndrome has not been identified, and it may be precipitated by multiple underlying risk factors. Of these, abdominal obesity and insulin resistance appear most important (Grundy, 2005). There is currently debate surrounding the concept of a metabolic syndrome. A statement from the American Diabetes Association describes the need for additional data to confirm the veracity of this constellation as a true "syndrome". Until that time, they caution the use of this label for patients (Kahn, 2005). However, the metabolic syndrome is recognized as a major health risk by the World Health Organization (WHO), American Heart Association, and U.S. National Cholesterol Education Program Panel (Despres, 2006; Grundy, 2006).

Table 1-15 Diagnostic Criteria for Metabolic Syndrome

Any 3 of 5 Criteria Constitute a Diagnosis of Metabolic Syndrome	Categorical Cut Points
Elevated waist circumference	≥102 cm (≥40 inches) in men
	≥88 cm (≥35 inches) in women
Elevated TG levels	≥150 mg/dL
	or
	Drug treatment for elevated TG levels[a]
Reduced HDL levels	<40 mg/dL in men
	<50 mg/dL in women
	or
	Drug treatment for reduced HDL levels[a]
Elevated BP	≥130 mm Hg systolic BP
	or
	≥85 mm Hg diastolic BP
	or
	Drug treatment for hypertension
Elevated fasting glucose levels	≥100 mg/dL
	or
	Drug treatment for elevated glucose levels

BP = blood pressure; HDL = high-density lipoprotein; TG = triglyceride.

[a] Fibrates and nicotinic acid are the most commonly used drugs for elevated TG and reduced HDL. Patients taking these drugs are presumed to have high TG and low HDL levels.

Modified from Grundy, 2005, with permission.

This syndrome is common, and approximately 20 to 25 percent of U.S. adults meet diagnostic criteria. Although the genders appear

equally affected, Mexican Americans show the highest prevalence, and incidence appears to increase in all ethnicities with age (Ford, 2002). The sequelae associated with metabolic syndrome are significant and include an increased risk of type 2 diabetes and mortality from coronary heart disease CVD, and all causes (Lorenzo, 2003; Malik, 2004; Sattar, 2003). Among those with metabolic syndrome, risks are further increased by cigarette smoking and elevated LDL cholesterol levels.

TREATMENT

Goals of clinical management include reducing risks for clinical atherosclerotic disease and for type 2 diabetes mellitus. Accordingly, primary therapy for metabolic syndrome focuses on lifestyle modification, particularly weight reduction and increased exercise. During evaluation, each metabolic syndrome component should be addressed and treated in accordance with current guidelines. Moreover, drug therapy should follow current guidelines for treatment of each individual component (Eberly, 2006; Grundy, 2006; National Cholesterol Education Program, 2001).

Dyslipidemia

HYPERCHOLESTEROLEMIA

Screening and Diagnosis

Data support that low-density lipoprotein cholesterol (LDL) is the primary atherogenic agent. Although previously believed merely to collect passively within vessel walls, LDL is now felt to be a potent proinflammatory agent and creates the chronic inflammatory response characteristic of atherosclerosis (Maron, 2004). Logically, elevated levels of total and LDL cholesterol are associated with increased rates of coronary artery disease, ischemic stroke, and other atherosclerotic vascular complications (Horenstein, 2002; Law, 1994).

Preventively, the National Cholesterol Education Program Adult Treatment Panel-III (ATP-III) (2001) recommends that all adults 20 years and older have a serum lipoprotein profile drawn after a 9- to 12-hour fast once every 5 years. This profile includes total, LDL, and high-density lipoproteins and triglycerides. Table 1-16 lists interpretation of these levels. However, if other co-morbid risks for coronary heart disease are present, then LDL goals are more stringent.

Table 1-16 Interpretation of Cholesterol and Triglyceride Levels

Lipoprotein Type (mg/dL)	**Interpretation**
Total cholesterol	
<200	Optimal
200â€“239	Borderline elevated
≥240	Elevated
LDL cholesterol	
<100	Optimal
100â€“129	Near optimal
130â€“159	Borderline elevated
160â€“189	Elevated
≥190	Very elevated
HDL cholesterol	

<40	Low
≥60	Elevated
Triglycerides	
<150	Optimal
150â€“199	Borderline elevated
200â€“499	Elevated
≥500	Very elevated

HDL = high-density lipoprotein; LDL = low-density lipoprotein.

Treatment

Lowering LDL cholesterol levels has been associated with reduced rates of myocardial infarction and stroke (Goldstein, 2006; Sever, 2003; Thavendiranathan, 2006). As seen in Table 1-17 and Fig. 1-9, therapy may include lifestyle changes with or without the addition of medication.

Table 1-17 Oral Lipid Lowering Agents

Drug Class and Agents	Brand Name	Major Indications	Starting Dose	Maximal Dose	Contraindications
HMG CoA reductase inhibitors 'statins'		Elevated LDL			Absolute: ▪ Active or chronic liver disease ▪ Pregnancy, lactation
Lovastatin	Mevacor, Altocor		20 mg qd	80 mg qd	
Pravastatin	Pravachol		40 mg qhs	80 mg qhs	
Simvastatin	Zocor		20 mg qhs	80 mg qhs	
Fluvastatin	Lescol		20 mg qhs	80 mg qhs	
Atorvastatin	Lipitor		10 mg qhs	80 mg qhs	
Rosuvastatin	Crestor		10 mg qhs	40 mg qhs	
Bile acid sequestrants		Elevated LDL			Absolute: ▪ Dysbetalipoproteinemia ▪ TG <400 mg/dL
Cholestyramine	Questran		4 g qd	24 g qd	
Colestipol	Colestid		2 g qd	16 g qd	
Colesevelam	Welchol		3750 mg qd	4375 mg qd	
Nicotinic acid		Elevated LDL, low HDL, elevated TG			Absolute: ▪ Chronic liver disease ▪ Peptic ulcer disease ▪ Severe gout
Immediate-release			100 mg tid	2 g tid	
Sustained-release			250 mg bid	1.5 g bid	
Extended-release	Niaspan		500 mg qhs	2 g qhs	
Fibric acids derivatives		Elevated TG, elevated			Absolute:

		remnants			■ Severe renal or liver disease ■ Gallbladder disease ■ Pregnancy, lactation
Gemfibrozil	Lopid, Gemcor		600 mg bid	600 mg bid	
Fenofibrate	Tricor		145 mg qd	145 mg qd	
Cholesterol absorption inhibitors		Elevated LDL			Relative: ■ Moderate or severe liver disease
Ezetimibe	Zetia		10 mg qd	10 mg qd	
Combination agent		Elevated LDL			Absolute: ■ Liver disease ■ Pregnancy, lactation
Ezetimibe/simvastatin	Vytorin		10 mg/10 mg qd	10 mg/80 mg qd	

bid = twice daily; CHD = coronary heart disease; GI = gastrointestinal; HDL = high-density lipoprotein cholesterol; HMG CoA = 3-hydroxy-3methylglutaryl coenzyme A; LDL = low-density lipoprotein cholesterol; TG = triglycerides; qd = daily; qhs = at bedtime; tid = three times daily; WHO = World Health Organization.

Cyclosporine, macrolide antibiotics, various antifungal agents, and cytochrome Pâ€“450 inhibitors should be used with appropriate caution with fibrates and niacin.

For those with depressed HDL levels, efforts should be directed toward reaching LDL goals. Additionally, weight management and increased physical activity should be included.

HYPERTRIGLYCERIDEMIA

Triglycerides are delivered to tissues by very-low-density lipoprotein (VLDL), which is synthesized and secreted by the liver. This triglyceride-rich lipoprotein is taken up by adipose tissue and muscle, where triglycerides are cleaved from VLDL. Ultimately, a VLDL remnant is created that is atherogenic. For this reason, triglyceride levels can be used as one marker for atherogenic lipoproteins, and high triglyceride levels have been linked to increases in cardiovascular disease (Assmann, 1996; Austin, 1998). Additionally, its clinical importance is underscored by its inclusion as a criterion for the metabolic syndrome (see Table 1-15) (Dunbar, 2005).

Hypertriglyceridemia is diagnosed based on criteria found in Table 1-16. For most with mild or moderate triglyceride elevation, recommendations from ATP-III attempt to lower both LDL and VLDL levels. Alternatively, for those with triglyceride levels greater than 500 mg/dL, treatment goals focus primarily on triglyceride levelâ€"lowering to prevent pancreatitis.

Stroke

Stroke is the third leading cause of death in the United States, and each year approximately 373,000 American women suffer a new or recurrent stroke. Primary prevention is important, as greater than 70 percent of strokes are first events (American Heart Association, 2005). Primary care providers should be aware of modifiable risk factors for stroke and treat or refer women for treatment of these factors (Table 1-18).

Table 1-18 Risk Factors and Treatment Results for Stroke

Risk Factor	Relative Risk	Relative Risk Reduction with Treatment
Hypertension	2â€"5	38%
Atrial fibrillation	1.8â€"2.9	68% with warfarin, 21% with aspirin
Diabetes	1.8â€"6	No proven effect
Smoking	1.8	50% at 1 year, baseline risk at 5 years postcessation

Exercise

Exercise has known benefits in preventing coronary artery disease, type 2 diabetes, osteoporosis, obesity, depression, insomnia, and breast and colon cancers (Brosse, 2002; Knowler, 2002; Lee, 2003; Vuori, 2001; Youngstedt, 2005). Many of these associations may result from the effects of exercise to lower blood pressure, decrease LDL cholesterol and triglyceride levels, increase HDL cholesterol levels, improve blood sugar control, and reduce weight (Braith, 2006; Pescatello, 2004; Sigal, 2004).

Despite these benefits, based on 2004 U.S. statistics, 66 percent of all women do not participate in leisure-time physical activity lasting longer than 10 minutes, and only 9 percent exercised more than 5 times per week (Lethbridge-Cejku, 2006). Recommendations from the Centers for Disease Control and Prevention (2006) include moderate-intensity activity such as walking, water aerobics, or yardwork for at least 30 minutes on 5 or more days each week *or* vigorous-intensity activities such as running, swimming laps, or circuit weight training for 20 to 60 minutes per session on at least 3 days each week. A fuller listing of general physical activities and their intensity descriptions can be found at the CDC website:

http://www.cdc.gov/nccdphp/dnpa/physical/pdf/PA_Intensity_table_2_1.pdf .

Although exercise programs have traditionally emphasized dynamic, aerobic lower-extremity exercise, research increasingly suggests that complementary resistance training improves muscular strength and endurance, cardiovascular function, metabolism rate, coronary risk factors, and psychosocial well-being (Pollock, 2000). Table 1-19 compares the different advantages offered by aerobic and resistance training.

Thyroid Disease

Dysfunction of the thyroid gland may lead to increased or decreased gland activity. As a result, symptoms of thyroid disease may vary widely, but commonly include changes in weight, temperature tolerance, menstruation, energy level, mood, skin and hair, and gastrointestinal motility. The risk of thyroid disease increases with age, and dysfunction is significantly more common in women.

Accordingly, the American Thyroid Association recommends that adults, especially women, be screened for thyroid dysfunction by measurement of a serum thyroid-stimulating hormone (TSH) concentration, beginning at age 35 years and every 5 years thereafter (Ladenson, 2000). Moreover, individuals with clinical manifestations potentially attributable to thyroid dysfunction and those with risk factors for its development may require more frequent testing. People at higher risk for thyroid dysfunction include the elderly, postpartum women, those with prior exposure to high levels of radiation (>20 mGy), and those with Down syndrome. In contrast, the U.S. Preventive Services Task Force (2004) has found insufficient evidence to recommend for or against routine screening.

Mental Health

DEPRESSION, DOMESTIC VIOLENCE, AND SUBSTANCE ABUSE

These problems are pervasive and account for significant morbidity and mortality. Each is discussed in detail in Chapter 13, Common Psychiatric Presentations, and should be routinely screened for at annual visits. For depression, few data support the use of one specific screening method, and simple questions such as "During the past 2 weeks, have you felt down, depressed, or hopeless?" and "Have you felt little interest or pleasure in doing things?" are often effective (Whooley, 1997). All positive screening tests should prompt evaluation for depression as outlined in Chapter 13 (see Table 13-5).

The American College of Obstetricians and Gynecologists (2002) guidelines on domestic violence recommend that physicians routinely ask women direct, specific questions about abuse. General introductory statements such as "Because abuse and violence are so common in women's lives, I've begun to ask about it routinely" and providing The National Domestic Safety Hotline number 1-800-799-SAFE (7233) may be used (American Medical Association, 1992).

Smoking

Cigarette smoking is the single most preventable cause of death in the United States and has been linked with certain cancers, cardiovascular disease, chronic lung diseases, and stroke (National Cancer Institute, 2004). Yet despite these known effects, in 2003, only 64 percent of U.S. smokers who had routine examinations were advised by a physician to quit smoking (Torrijos, 2006). Strategies for cessation may include counseling and pharmacotherapy, and both yield increased abstinence rates (Ranney, 2006).

Smoking Pharmacotherapy

Nicotine is the key addictive component of tobacco, and it binds to the nicotinic acetylcholine (Ach) receptor (Coe, 2005; Tapper, 2004). Binding increases central nervous system (CNS) dopamine levels. With smoking cessation, CNS dopamine levels are immediately lowered and cravings follow.

To blunt withdrawal symptoms, several products have been developed. These pharmacologic agents can broadly be divided into (1) nicotine replacement agents, (2) CNS agents, and (3) nicotine agonists (Table 1-20). Of these, nicotine replacement agents lower nicotine levels gradually, thereby blunting nicotine withdrawal symptoms, and increasing the probability of smoking cessation. Of the CNS agents, bupropion is a dopamine reuptake inhibitor. This drug may maintain central levels of dopamine during cessation and diminish dopamine withdrawal symptoms. Finally, varenicline is a nicotinic Ach-receptor partial agonist. In theory, varenicline (Chantix, Pfizer, New York, NY) binds to the nicotinic Ach receptor to relieve withdrawal symptoms. All of these are effective. Wu and colleagues (2006), however, in their meta-analysis of controlled trials found higher rates of cessation after 1-year following varenicline.

Table 1-20 Drugs Used for Smoking Cessation					
Agent	**Brand Name**	**Initial Dosing**	**Maintenance**	**Drug Tapering**	**Therapy Duration**
Nicotine replacement					
Patch	Habitrol Nicoderm CQ	For those smoking >10 cigs/d: a 21-mg patch is reapplied daily	After 2 wks, 14-mg patch is used	For the final 2 wks, a 7-mg patch is used for both groups	8-12 wks

Alcohol Abuse

Simple direct questions regarding use can be brief yet effective tools to identify potential alcohol abuse (Fleming, 2005). If usage patterns suggest abuse, then further evaluation or referral is warranted. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV-TR) criteria for substance dependence or substance abuse are found in Tables 13-9 and 13-10.

INSOMNIA

Insomnia is common and its definition includes: (1) difficulty initiating sleep, (2) trouble maintaining sleep, and (3) early waking. Insomnia may be primary or may be secondary to other conditions such as depression, cross-time-zone travel, restless leg syndrome, stimulant use, and sleep apnea (National Institutes of Health, 2005). Accordingly, a historical inventory should be taken to investigate such complaints and treatment should be directed to these and other secondary causes (Becker, 2005).

Treatment of primary insomnia is typically cognitive-behavioral or pharmacologic. Behavioral therapies are varied and include those that control sleep timing and duration, attempt to improve the bedroom environment, or focus on relaxation techniques (Silber, 2005). Medications may be used to aid sleep, and most agents are of the benzodiazepine family (Table 1-21).

Table 1-21 Medications for Insomnia Approved by the U.S. Food and Drug Administration

Medication	Duration of Action	Dose	Indications
Benzodiazepines			
Temazepam (Restoril)	Intermediate	7.5â€“30 mg	For sleep-maintenance insomnia
Estazolam (ProSom)	Intermediate	0.5â€“2 mg	For sleep-maintenance insomnia
Triazolam (Halcion)	Short	0.125â€“0.25 mg	For sleep-onset insomnia
Benzodiazepine-receptor agonists			
Eszopiclone (Lunesta)	Intermediate	1â€“3 mg	For sleep-maintenance insomnia
Zolpidem (Ambien)	Short	5â€“10 mg	For sleep-onset insomnia
Zaleplon (Sonata)	Ultrashort	5â€“20 mg	For sleep-onset or sleep-maintenance insomnia
Melatonin-receptor agonist			
Ramelteon (Rozerem)	Short	8 mg	For sleep-onset insomnia

TECHNIQUES USED FOR IMAGING IN GYNECOLOGY: INTRODUCTION

Over the past several decades, there have been a number of technical advances that currently allow for superb imaging of female pelvic structures. The evolution of sonography has led to use almost equivalent to that in obstetrics. Radiography and contrast hysterosalpingography (HSG) have all but been replaced by computed-tomographic (CT) scanning with its excellent pelvic organ resolution. In addition, magnetic resonance (MR) imaging is now readily available in most centers and has literally added new dimensions to pelvic imaging.

SONOGRAPHY

Physics

In sonography, the image displayed on a screen is produced by sound waves reflected back from an imaged structure. Alternating current is applied to a transducer containing piezoelectric crystals, which convert electric energy to high-frequency sound waves. A water-soluble gel applied to the skin acts as a coupling agent. Sound waves pass through layers of tissue, encounter an interface between tissues of different densities, and are reflected back to the transducer. Converted back into electric energy, they are displayed on a screen. Dense material such as bone, or a synthetic material such as an intrauterine device, produces high-velocity reflected waves, also termed *echoes* , which are displayed on a screen as white. Materials such as these are described as *echogenic* . Conversely, fluid is anechoic, generates few reflected waves, and appears black on a screen. Images are generated so quicklyâ€”more than 40 frames/secondâ€"that the picture on the screen appears to move in real-time (Cunningham, 2005b).

Reflection of sound is greatest when there is a large difference between the acoustic impedance of two structures, which explains why cysts are so well demonstrated with sonography. Strong echoes are produced from the cyst walls but no echoes arise from fluid within the cyst. As more sound traverses the cyst, more echoes are received from the area behind the cyst, a feature known as *through-transmission* or *acoustic enhancement* (Fig. 2-1). Conversely, with a calcified structure, there is a reduction in sound passing through, which causes a band of reduced echoes beyond it, known as *acoustic shadowing* (Fig. 2-2) (Armstrong, 2001).

Examination Techniques

Guidelines for sonographic examination of the female pelvis have been established by the American Institute of Ultrasound in Medicine (2005). These were developed to serve as standards of quality assurance for patient care and to provide assistance to practitioners performing sonography. Guidelines describing equipment and documentation may be accessed at http://www.aium.org/publications/clinical/pelvis.pdf .

All probes should be cleaned after each examination, and vaginal probes should be covered by a protective condom sheath prior to insertion. A female staff member should always chaperone patients undergoing transvaginal sonography (TVS). Guidelines describe the examination to be performed for each organ and anatomic region in the female pelvis. For instance, in evaluating the uterus, the following should be documented: uterine size, shape, and orientation; and a description of the endometrium, myometrium, and cervix. A permanent record of the examination and its interpretation should be appropriately labeled and placed in the medical record. A copy is also kept by the facility performing the study.

TRANSABDOMINAL SONOGRAPHY

A variety of examination techniques can be used for the sonographic study of the female pelvis. In a nonpregnant woman, transabdominal evaluation, using a curved-array 3- to 5-mHz transducer, is still considered the first approach because it provides global identification of all pelvic organs and their special relationships to one another (American Institute of Ultrasound in Medicine, 2005). A full bladder is usually necessary for adequate visualization, as it pushes the uterus upwards from behind the pubic symphysis and displaces small bowel from the field of view. Moreover, the bladder acts as an acoustic window to improve transmission of sound waves. In patients with large lesions or masses located superior to the bladder dome, only the panoramic capabilities provided by transabdominal sonography allow complete evaluation of the disease process (Fleischer, 1997a). Still, evaluation of the endometrial cavity may be problematic with a transabdominal approach, often necessitating the use of the transvaginal technique.

TRANSVAGINAL SONOGRAPHY

This modality uses higher-frequency (5- to 10-mHz) transducers, which increase sensitivity and spatial image resolution. The probe is positioned in the vaginal fornices, thus the transducer is closer to the region of interest, and there is less beam attenuation in superficial soft tissues. In contrast to transabdominal imaging, the bladder is emptied prior to performing a transvaginal study.

TRANSRECTAL AND TRANSPERINEAL TECHNIQUES

Transrectal probes or conventional transducers placed over the perineal region are much less commonly employed. They are used for selected indications such as those discussed further in the section on pelvic floor imaging (Pelvic Floor).

HARMONIC IMAGING

This recent modification of sonography is designed to improve tissue visualization by reducing artifacts, particularly those that arise from superficial structures such as adipose tissue, by using harmonics of the transmitted ultrasound beam (Armstrong, 2001).

FOCUSED ULTRASOUND THERAPY

Ultrasound energy during conventional imaging propagates harmlessly through tissue with small amounts of energy being absorbed. This energy is deposited as heat but is dissipated by the cooling effects of perfusion and conduction. No harmful effects have been recorded at the intensities used for diagnostic purposes (American Institute of Ultrasound in Medicine, 1991).

If, however, the ultrasound beam carries a high level of energy and is brought to a tight focus, energy carried by the beam is rapidly converted into heat with an increase in temperature (ter Haar, 1999). When target spot temperatures rise higher than 55Â°C, proteins are denatured, cell death occurs, and coagulative necrosis is created (Lele, 1977). In contrast, surrounding tissues are warmed, but not to lethal temperatures. This technique may be used in the treatment of leiomyomas and discussed later in the chapter.

DOPPLER TECHNOLOGY

This modality can be performed with either transabdominal or transvaginal sonography to determine blood flow through pelvic organs. Of Doppler parameters, the resistive index and pulsatility index are commonly calculated. These describe the impedance to blood flow within and to the organ of interest.

Applications of color Doppler in gynecology include evaluation of ovarian masses for torsion or malignancy, improved detection of extrauterine vascularity associated with ectopic pregnancy, and assessment of uterine perfusion in patients with leiomyomas and endometrial disorders.

Saline-Infusion Sonography

Also called sonohysterography, saline-infusion sonography (SIS) was developed to obtain a more detailed view of the endometrial cavity (Hill, 1997). After voiding, a woman undergoes a comprehensive transvaginal sonographic evaluation. A vaginal speculum is then inserted, the vagina and cervix are swabbed with an antiseptic solution, and a catheter primed with sterile saline is advanced into the cervical canal and past the internal os. We do not routinely use a tenaculum for this. Touching the uterine fundus when advancing the catheter should be avoided, as this can induce pain or vasovagal response. It may also shear away endometrium, causing false-positive results. The speculum is carefully removed to avoid dislodging the catheter, the transvaginal probe is reinserted, and sterile saline is injected through the catheter at a rate based on the patient's tolerance. Usually not more than 10 to 20 mL is required to distend the endometrial lumen (Fig. 2-3). During this time, the cavity is observed with transvaginal sonography. The sonographer scans in the longitudinal plane, imaging from one cornu to the other, and in the transverse plane from the fundus to the cervix. Any irregularities of the endometrial surface are well-delineated by the hypoechoic contrast of the saline. At the procedure's conclusion, the catheter is withdrawn under sonographic visualization so that the uterine isthmus and endocervical canal may be evaluated. On average, the procedure lasts 5 to 10 minutes.

There are many different catheter systems, including rigid systems and flexible catheters with and without attached balloons. We

use a 7F hysterosalpingography (HSG) balloon catheter set (Cooper Surgical, Trumball, CT) and have found it easy to place and well tolerated (Fig. 2-4). Several distending solutions have been described, including saline, lactated Ringer solution, and 1.5-percent glycine. We have found that sterile saline is inexpensive and provides excellent imaging.

In the premenopausal woman, SIS is best performed within the first 10 days of the menstrual cycle, and optimally on cycle days 4, 5, or 6, when the endometrial lining is thinnest. This timing is recommended to avoid misinterpretation of menstrual blood clots as intrauterine pathology or conversely, to miss pathology obscured by thick endometrial growth (Hill, 1997). In addition, such timing should usually preclude pregnancy. For the postmenopausal woman, timing of the procedure is not cycle-dependent.

Complications of SIS are minimal, and the risk of infection is less than 1 percent (Bonnamy, 2002). Most recommend prophylactic antibiotics for women with a history of pelvic inflammatory disease and in those who require bacterial endocarditis prophylaxis. We also routinely give a single dose of doxycycline, 200 mg orally, following SIS in women with diabetes. Although not evidence-based, we also choose to provide prophylaxis to infertile patients because of the risk for significant tubal damage associated with pelvic infection. Pain is usually minimal. During SIS, it has been our experience that women who have undergone tubal ligation have more discomfort, likely because fluid cannot efflux through the tubes. A nonsteroidal anti-inflammatory drug given 30 minutes prior to the procedure will typically minimize any potential discomfort.

Contraindications to SIS include hematometra, pregnancy, active pelvic infection, or obstruction such as with an atrophic or stenotic cervix or vagina. In postmenopausal women with cervical stenosis, we have found use of a paracervical block, a tenaculum for traction on the cervix, and a sonographically-guided sequential cervical dilation with lacrimal duct dilators to be helpful.

Normal Anatomy with Sonography

REPRODUCTIVE TRACT ORGANS

In the reproductive years, a normal uterus measures approximately 7.5 × 5.0 × 2.5 cm, but is smaller in the prepubertal, postmenopausal, or hypoestrogenized woman. Normal uterine stroma returns low-level, uniform echoes, and the position of the endometrial and endocervical canals is indicated by linear echogenic stripes, representing the interfaces between mucus and mucosa (Fig. 2-5). The cervix is best visualized transvaginally with the tip of the probe about 2 to 3 cm from it. The endocervical

canal is a continuation of the endometrial cavity and appears as a thin echogenic stripe (Fig. 2-6). The vagina is seen as a hypoechoic tubular structure with an echogenic lumen that curves inferiorly over the muscular perineal body at the introitus. The ovaries are ellipsoid, and normally lie in the ovarian fossa with their long axes parallel to the internal iliac vessels and the ureters, which lie posteriorly (Fig. 2-7). Ovarian volume ranges from 4 to 10 cm^2 depending on hormonal status (Cohen, 1990). Ovarian follicles appear as spherical anechoic structures within the ovary and may reach a normal size of 2.5 cm. Normal fallopian tubes are not visible. A small amount of fluid in the posterior cul-de-sac is a normal finding and is often seen with ovulation.

ENDOMETRIUM

Functionally, the endometrium has two main layers: the stratum basale, which comprises the densely cellular supporting stroma and varies little with the phase of the cycle, and the stratum functionale, which proliferates during each cycle and partially desquamates at menses (see Fig. 8-2). These layers cover the entire cavity.

Sonographic appearances of the endometrium during the menstrual cycle correlate with the phasic changes in its histologic anatomy. During the follicular phase, when the endometrium is under the influence of estrogen from ovarian folliculogenesis, the stratum basale appears echogenic due to spectral reflections from the mucus-laden glands. In contrast, the stratum functionale is relatively hypoechoic because of the orderly arrangement of glands that lack secretions. The central opposing surfaces of these two endometrial layers manifest as a highly reflective, thin midline strip, and the three echogenic lines give a characteristic tri-laminar appearance of the proliferative endometriumâ€"the endometrial stripe (Figs. 2-8 and 8-6).

FIGURE 2-8

Transvaginal sonogram in the sagittal plane of the characteristic tri-laminar proliferative endometrium. Calipers demonstrate proper measurement of the "double-layer" thickness made of the alternating hyper-hypo-hyperechogenic lines. *(Courtesy of Dr. Elysia Moschos.)*

Endometrial thickness is measured from the echogenic interface of the anterior basale layer to the echogenic interface of the posterior basale layer, thus representing a "double thickness". The hypoechoic halo outside of and adjacent to the endometrium should not be included in the measurement, as this is actually the inner compact layer of myometrium. Sonographically, the endometrium should be measured from a sagittal or long-axis image of the uterus in the plane in which the endometrial stripe is seen contiguous with the endocervical canal and distinct from the myometrium. Endometrial thickness correlates approximately with the day of the cycle up to day 7 or 8 (Richenberg, 2000).

With ovulation and progesterone production from the corpus luteum during the secretory phase, glandular enlargement and appearance of secretory vacuoles begins. These changes are seen sonographically (Fig. 2-9). During this phase, the endometrium achieves its maximum thickness as the stroma becomes more vascular and edematous.

With menstruation, the endometrium appears as a slightly irregular echogenic interface from sloughed tissue and blood. The thinnest measurements of endometrium are found at the conclusion of menses (Fig. 2-10).

With cessation of estrogen stimulation beginning at menopause, the endometrium atrophies, and there is no further cyclic sloughing. The postmenopausal endometrium appears thin and uniform (Fig. 2-11).

PELVIC FLOOR

With the advent of urogynecology as a specialty, sonography is widely used to evaluate pelvic floor anatomy and function. Various two-dimensional techniques, including transvaginal, transrectal, transperineal, and intraurethral sonography, have been used to investigate urethral anatomy.

Transrectal sonography was the first technique used to assess anal sphincter morphology after childbirth. This method requires special equipment as well as distension of the anal canal (see Chap. 25, Endoanal Ultrasonongraphy). The technique is of limited value during the immediate postpartum period, and it only provides information about anal sphincter morphology. Thus, without levator ani muscle assessment, it cannot be used to completely evaluate the posterior compartment (Wisser, 2001).

Alternatively, assessment of anorectal morphology and the pelvic floor have been described with vaginal sonography. This approach uses a rotating endorectal probe or standard transvaginal probe (Sandridge, 1995; Sultan, 1994).

Perineal sonography has been used more recently to evaluate the pelvic floor. The technique requires filling the bladder with approximately 300 mL of saline. With a woman either supine or erect, a 5-MHz curved-array transducer is placed in a sagittal orientation to the perineum. This allows real-time imaging of the symphysis, urethra, bladder neck, and bladder. Measurements have been standardized by Schaer and colleagues (1995).

Clinical Applications

Transvaginal sonography (TVS) is preferred for evaluation of the normal uterus and adnexa and for diagnosis of gynecologic diseases. These include diagnosis and management of ectopic pregnancy, support for infertility practices, and early detection of ovarian and endometrial cancer.

Transvaginal sonography has few limitations. The only two absolute contraindications are imperforate hymen and patient refusal. A relative contraindication is the patient with a virginal or strictured introitus. These women, however, can usually undergo comfortable examination with proper counseling.

LEIOMYOMAS

When visualized with sonography, uterine leiomyomas usually appear as solid, discrete, well-defined masses with a thin hypoechoic periphery (Fig. 2-12). Although most often hypoechogenic in relation to the myometrium, they may also appear hyper- or isoechogenic (see Fig. 9-6) (Lyons, 2000). Shadowing at their lateral borders is common.

FIGURE 2-12

Transvaginal sonogram of a fundal subserosal leiomyoma (**arrow**). *(Courtesy of Dr. Elysia Moschos.)*

Sonography is used by most as the imaging technique for preoperative assessment of women who undergo uterine artery embolization (UAE) for symptomatic leiomyomas. In these women, three-dimensional color Doppler sonography can accurately depict fibroid vascularity, and in some cases, collateral flow is seen that is not detected by uterine arteriography (Muniz, 2002). Doppler flow measurements are also useful to predict outcomes of leiomyoma embolization such as tumor shrinkage and treatment failure (McLucas, 2002). Sonography can also be used to document volume decreases of leiomyomas following gonadotropin-releasing hormone (GnRH) agonist therapy (Fleischer, 2000).

ADENOMYOSIS

Sonographic diagnosis of adenomyosis is difficult and based on findings that may be very subtle. When evaluated by Doppler sonography, adenomyosis lesions are vascularized and vessels appear less well-organized than those in the normal myometrium (Atri, 2000; Reinhold, 1999). Although MR imaging is still considered the gold standard for diagnosis of adenomyosis, careful analysis of these transvaginal sonographic findings has shown greater than 80-percent sensitivity and 70-percent specificity (Fedele, 1992; Reinhold, 1995).

ENDOMETRIAL ABNORMALITIES

Transvaginal sonography is used to accurately evaluate the thickness and appearance of the endometrium, and together with SIS, plays an important role in the management of endometrial disorders. It is commonly employed to aid in three areas: (1) determining which women should undergo endometrial biopsy, (2) analyzing the endometrium to detect polyps or submucosal

leiomyomas, and (3) assessing myometrial invasion from endometrial cancer (Fleischer, 1997b).

Transvaginal Sonographic Endometrial Evaluation

The clinical usefulness of sonography in women with postmenopausal bleeding relies on the ability to accurately measure endometrial thickness (see Chap. 8, Transvaginal Sonography). The thickest point along the endometrium from the anterior to posterior endometrial-myometrial junction is measured. In postmenopausal women with endometrial measurements of 5 mm or less, sonographic-pathologic studies have demonstrated that bleeding can be attributed to endometrial atrophy (Goldstein, 1990; Granberg, 1991). Endometrial hyperplasia, polyps, and carcinoma typically have thicker endometrial measurements.

A number of studies have been done to evaluate the capability of sonography to identify normal echostructural changes and pathology in the postmenopausal endometrium. For example, cystic endometrial changes implicate polyps, homogeneously thickened endometrium suggests hyperplasia, and a heterogeneous structural pattern prompts suspicion of malignancy. However, these sonographic findings show much overlap and cannot be used alone (Atri, 1994; Doubilet, 2000; Hulka, 1994; Levine, 1993). Additionally, Doppler studies of endometrial vasculature are not informative, because there are no significant differences between resistive and pulsatility indices in benign versus malignant causes of endometrial thickening (Bourne, 1995; Sheth, 1993).

Once diagnosed, determining the local extent of endometrial carcinoma is accurate using transvaginal sonography. Direct myometrial extension can be assessed; however, false-positive findings may be caused by compression and thinning of the myometrium from large benign lesions. In addition, color Doppler sonography of the myometrial vessels may help to identify invasive endometrial carcinoma. Although useful in evaluating the depth of myometrial invasion, sonography is *not* used to stage endometrial cancer because of its limited ability to evaluate disease beyond the corpus.

Saline-Infusion Sonographic Endometrial Evaluation

In addition to conventional TVS, SIS has also been used to evaluate the endometrium in various clinical situations (Lindheim, 2003a). Among others, these include abnormal uterine bleeding, clarification of endometrium thickening or other endometrial lesions, visualization of the endometrial stripe when poorly imaged because of uterine position or pathology, monitoring tamoxifen therapy, and some infertility investigations.

Defining Endometrial Lesions

In further defining endometrial thickening, SIS is the best nonoperative procedure for diagnosing polyps (see Chap. 8, Saline-Infusion Sonography). The focal nature of these lesions is contrasted with the diffuse endometrial thickening seen with endometrial hyperplasia. Moreover, polyps and submucosal leiomyomas can often be differentiated based on two findings (Jorizzo, 2001). The first are differences in echotextureâ€”the leiomyoma is hypoechoic, similar to the myometrium, whereas the polyp is hyperechoic (Fig. 2-13). The second feature is demonstration of the endometrial mucosal surface, which divides the leiomyoma from the endometrial lumen (Jorizzo, 2001).

Obviously, SIS cannot be used to differentiate between benign lesions and malignancies with absolute certainty. Thus, many women with an endoluminal mass require histological evaluation to exclude malignancy (Dubinsky, 1999; Fleischer, 1997c; Jorizzo, 1999, 2001; Parsons, 1993).

Saline-infusion sonography is more accurate than either TVS or hysteroscopy to identify size, location, and depth of myometrial involvement of submucosal leiomyomas (Cicinelli, 1995). This is useful to predict outcomes and complications of hysteroscopic resection (Section 41-37, Hysteroscopic Myomectomy) (Bradley, 2000; Emanuel, 1995).

Monitoring Tamoxifen Therapy

In women taking tamoxifen, SIS is more useful than TVS. Saline-infusion sonography helps to delineate hyperplastic conditions in those women who have uterine bleeding when taking tamoxifen, whereas in the asymptomatic woman, SIS appears to add little value (Bertelli, 2000; Hann, 2001).

Evaluation of Infertility

Many infertility specialists are now incorporating SIS as a first-line screening tool for uterine evaluation before embryo transfer in women undergoing in vitro fertilization (IVF), ovum donation, and IVF-surrogacy (Kim, 1998; Lindheim, 1998; Serafini, 1998). In those with a history of recurrent abortion, SIS has been used to demonstrate not only mÃ¼llerian anomalies, but also a variety of other uterine cavity defects (Keltz, 1997). As a screening tool in this setting, it appears to be twice as accurate as hysterosalpingography and TVS (Soares, 2000).

Other Uses

Other diagnostic and therapeutic applications of SIS have been described. It may be used to locate a "lost" IUD and determine whether it is embedded in the myometrium (Bussey, 1996). It has been used to diagnose postabortal remnants, including placenta accreta, and to assess previous cesarean delivery scars (Monteagudo, 2001; Tal, 1997). Coccia and colleagues (2001) used pressure lavage under ultrasound guidance (PLUG) to treat intrauterine adhesions in seven women. This technique uses continuous accumulation of saline for the mechanical disruption of synechiae. Saline-infusion sonography can also guide direct biopsy of intrauterine pathology such as polyps (Bernard, 2002; Dubinsky, 2000; Lindheim, 2003b). Limitations primarily involve issues of technical feasibility, such as cervical stenosis or poor visualization due to leakage of saline with insertion of an operating instrument.

OVARY

Lesion Characterization

Sonography is commonly the initial and often the only imaging procedure performed in the evaluation of pelvic and ovarian masses. Simple cysts are one of the most common pelvic masses. The classic sonographic findings of simple cysts are smooth and regular margins, lack of internal echoes, and increased through-transmission or acoustic enhancement (see Fig. 2-1). Blood-filled cysts, such as hemorrhagic cysts and endometriomas, have variable appearances because of clot, lysis, and retraction. With these, internal echoes, septa, mural nodules, solid components, fluid-debris levels, and retracting clot can be seen. Some blood-filled cysts at first may appear to be solid, with an internal pattern of many small low-level echoes. However, consistent with a cyst, increased through-transmission is present (see Fig. 10-5). The sonographic characteristic that has been proven most important for the diagnosis of a hemorrhagic cyst versus an endometrioma is the change over time of its internal structure (see Fig. 9-11) (Derchi, 2001).

With ovarian neoplasms, some sonographic findings may be indicative. For example, a benign serous cystadenoma appears as a cystic mass containing clear fluid with thin internal septations. Mural nodules are infrequent. However, there is no clear boundary between the sonographic appearance of a cystadenoma and a cystadenocarcinoma. As a general rule, the greater the amount of solid tissue within the mass, the higher the probability of malignancy. Criteria suggesting cancer are presence of thick septations, multiple papillary projections, solid portions within the mass, and ascites (see Table 9-4). Mucinous cystadenomas usually are also cystic, and compared with their serous counterparts, they tend to have multiple internal septations, more echogenic fluid, and fluid-debris levels within the cyst.

Mature cystic teratomas (dermoid tumors) have a classical sonographic appearance (see Fig. 2-2). As described in Chapter 9, Mature Cystic Teratoma (Benign Cystic Teratoma or Dermoid Cyst), these include a markedly hyperechogenic mass with a structure similar to that of surrounding fatty tissue, cystic areas with round echogenic mural nodules, and calcifications, tufts of hair, and fat-fluid levels. These findings reflect the unique tissue contrasts found in these benign tumors.

Malignant Characteristics

Sonography is the best diagnostic technique for preoperative determination of the malignant potential of an ovarian mass. To this end, scoring systems based on number and thickness of septa, presence and number of papillations, and proportion of solid tissue within the mass have been proposed to standardize the interpretation of findings (DePriest, 1993; Sassone, 1991). When morphology and structure of adnexal masses are combined with color Doppler and spectral analysis of flow signals, the specificity and positive predictive value of sonographic diagnosis is increased (Buy, 1996; Jain, 1994; Fleischer, 1993; Twickler, 1999). In a meta-analysis of 46 studies with 5,159 patients, Kinkel and colleagues (2000) reported significantly higher accuracy for combined sonographic techniques compared with that of each individual technique alone.

Neovascularity within a malignant neoplasm produces a significant increase in color Doppler flow signals. This assumption has led many investigators to evaluate presence, spatial distribution, and prevalence of flow signals within ovarian masses. Most malignant lesions appear well vascularized, with flow signals both in peripheral and central regions, whereas most benign tumors appear poorly vascularized. However, a firm diagnosis based on this alone is not possible. Indeed, both avascular malignant tumors as well as benign hypervascular masses have been reported (Brown, 1994; Kawai, 1992).

Neovascularity within malignancies is made up of abnormal vessels that lack smooth muscle and contain multiple arterio-venous shunts. Consequently, low-impedance flow is expected with such masses as shown in (Fig. 2-14) (Kurjak, 1992; Weiner, 1992). Other studies, however, demonstrated significant overlap between values from benign and malignant lesions (Jain, 1994; Levine, 1994; Stein, 1994).

Torsion

In evaluation of other ovarian pathology, color Doppler can be employed to diagnose ovarian torsion. Its sonographic appearance varies according to the degree of vascular compromise and presence of an adnexal mass. Color Doppler of vessels in the infundibulopelvic ligament may aid the specific diagnosis by demonstrating absent arterial and venous flow (see Fig. 9-15). Importantly, central venous signals in tubo-ovarian torsion are thought to indicate ovarian tissue viability (Fleischer, 1995).

PELVIC INFLAMMATORY DISEASE

Acute Infection

Although pelvic sonography is commonly performed in women with acute salpingitis, there are no large studies evaluating its sensitivity, specificity, or overall usefulness (Boardman, 1997; Cacciatore, 1992; Patten, 1990). Sonographic findings vary according to disease. In early infection, sonography may be normal. With progression, early nonspecific findings include free pelvic fluid, endometrial thickening, endometrial cavity distension by fluid or gas, and indistinct borders of the uterus and ovaries. Enlarged ovaries with increased numbers of small cystsâ€"a so-called "polycystic ovary appearance"â€"has been shown to correlate with pelvic inflammatory disease (PID). Cacciatore and colleagues (1992) found larger-than-normal ovarian volumes in women with endometrial-biopsy or laparoscopically-proven PID. They also documented decreasing ovarian size with treatment.

Sonographic findings of the fallopian tubes are the most striking and specific landmarks of PID (Fig. 2-15). Although normal tubes are rarely seen unless surrounded by ascites, an inflamed tube swells and the walls and endosalpingeal folds thicken, allowing visualization with sonography. As the lumen occludes distally, the tube distends and fills with fluid. A variety of appearances may result (Timor-Tritsch, 1998). The tube may become ovoid or pear shaped, filling with fluid that may be anechoic or echogenic. The tubal wall becomes thickened, measuring ≥5 mm, and incomplete septa-like structures are common as the tube folds back upon itself. If the distended tube is viewed in cross section it may demonstrate the cogwheel sign, due to thickened endosalpingeal folds (Timor-Tritsch, 1998). Typically the swollen fallopian tubes extend posteriorly into the cul-de-sac, rather than extending superiorly and anterior to the uterus as large ovarian tumors tend to do. Fluid-debris levels are often visualized in the dilated tubes and rarely, gas-fluid levels or echogenic bubbles of gas can be seen. Color and power Doppler show increased flow from hyperemia in

the walls, as well as incomplete septa of the inflamed tubes (Tinkanen, 1993).

Tubo-Ovarian Infection

As PID progresses, the ovary can become involved. When the ovary adheres to the tube, but is still visualized, it is called a *tubo-ovarian complex* . In contrast, a *tubo-ovarian abscess* is the result of a complete breakdown of ovarian and tubal architecture such that the separate structures are no longer identified (Fig. 2-16). If the contralateral side was not affected initially, it may become so. When both tubes are inflamed and occluded, the entire complex typically takes on a U-shape as it fills the cul-de-sac, extending from one adnexal region to the other (Horrow, 2004). The lateral and posterior uterine borders of the uterus become obscured and individual tubes and ovaries cannot be distinguished. In women not responding to medical therapy, sonography can be used to guide transvaginal drainage of these lesions (Kaakaji, 2000; Patten, 1990).

Findings of Prior Infection

Findings of chronic PID include hydrosalpinx. Several sonographic findings such as its tubular shape, incomplete septa, and hyperechoic mural nodules can help to distinguish a hydrosalpinx from other cystic adnexal lesions (see Fig. 9-18). If color flow is detected in a hydrosalpinx, it tends to be less exuberant than flow seen in acute PID. Molander and colleagues (2002) found a higher pulsatility index in patients with a chronic hydrosalpinx (1.5 Â± 0.1) than with acute PID (0.84 Â± 0.04).

A small number of women with prior PID may have a peritoneal inclusion cyst. This diagnosis is made when the ovary is surrounded by a loculated fluid collection with thin septations (Horrow, 2002). A peritoneal inclusion cyst forms when fluid from a ruptured ovarian cyst is trapped around the ovary by adhesions.

ECTOPIC PREGNANCY

Sonography plays a pivotal role in clinical management of suspected ectopic pregnancy. Because a simultaneous uterine and ectopic pregnancyâ€”a heterotopic pregnancyâ€”is rare, identification of a uterine pregnancy is the single most important finding

for exclusion of an ectopic gestation. Intrauterine pregnancy can be assured if a gestational sac, double-decidual sign, or embryo is found within the endometrial cavity. All pregnancies can induce an endometrial decidual reaction, but a double decidual signâ€”two echogenic external layers encircling the anechoic gestational sacâ€”is caused by invasion of the decidua parietalis and decidua capsularis of the developing placenta (Fig. 2-17).

Ectopic pregnancy may present with a large variety of sonographic patterns (see Fig. 7-5). An extrauterine gestational sac containing an embryo is an unequivocal finding; however, solid and complex adnexal masses in conjunction with an empty uterus and a positive pregnancy test result are frequently encountered. A complex adnexal mass is usually caused by hemorrhage within the ectopic sac, or by an ectopic pregnancy that has ruptured into the tube. Complex free fluid or blood clots are often associated (Filly, 1987; Fleischer, 1990; Nyberg, 1987). Placental blood flow within the periphery of the complex adnexal massâ€”the ring of fireâ€”can be seen with transvaginal color Doppler imaging (see Fig. 7-7). Although this can aid in the diagnosis, this finding can also be seen with a corpus luteum of pregnancy (Pellerito, 1992b).

GESTATIONAL TROPHOBLASTIC DISEASE

Sonography plays an important role in establishing the diagnosis of hydatidiform mole. A complete hydatidiform mole displays tissue that is interspersed with numerous punctate sonolucencies (Fig. 37-4). The appearance varies according to gestational duration and correlates with the size of hydropic villi (Jones, 1975). For example, molar pregnancies of menstrual age from 8 to 12 weeks typically appear as homogenously echogenic intraluminal tissue, and villi have a maximum diameter of 2 mm. With maturation, vesicles may approach 10 mm in diameter, and they are readily seen as sonolucent cystic spaces. These villi create a classic transabdominal image termed a "snowstorm" pattern. Fetal tissues and amniotic membranes are absent.

In contrast, features of a partial mole include hydropic placental degeneration and presence of concomitant fetus or fetal parts. Unfortunately, hydropic placental degeneration may give a similar sonographic appearance as hydatidiform molar tissue (Fleischer, 2001). Villi are swollen and edematous. These hydropic changes are seen sonographically in 20 to 40 percent of placentas from

aborted pregnancies (Reid, 1983). Thus, histologic, genetic, and immunologic analysis of tissue is typically required to differentiate between molar and nonmolar pregnancy (see Chap. 37, Immunostaining).

Theca-lutein cysts that enlarge under the influence of high serum levels of β-hCG are also commonly seen with molar pregnancies. They are typically bilateral and appear as multiloculated cystic masses that measure between 4 and 8 cm in diameter (Fleischer, 2001).

Sonography may also be used to assess possible invasive trophoblastic disease (Taylor, 1987). The sonographic appearance of invasive trophoblastic tissue is that of a focal irregular echogenic region within the myometrium. Doppler sonography can display the presence and relative aggressiveness of myometrial implants by depicting increased and typically turbulent flow to these tumors through the uterine arteries (Taylor, 1987). Sonography and Doppler analysis are also used to evaluate tumor response to chemotherapy (Hammond, 1980). Moreover, evaluation of the liver and kidney for metastatic disease may be aided by sonography (Munyer, 1981).

INFERTILITY

Sonography is employed for four main purposes in the approach to female infertility: (1) identification of abnormal pelvic anatomy; (2) detection of pathology causal or contributory to infertility; (3) evaluation of cyclic physiologic uterine and ovarian changes; and (4) surveillance and visual guidance during infertility treatment (Barnhart, 2000; Parsons, 2001).

Sonography can easily demonstrate anatomic uterine defects that may affect both gamete passage and ovum implantation. As discussed, conventional TVS can be used to visualize submucous leiomyomas and polyps; however, relationships of these lesions with the endometrial surface is better seen with SIS. Intrauterine synechiae, which can be seen as hypoechoic lines disrupting the echogenic endometrium by conventional sonography, are more definitively seen during SIS as echogenic bands extending from one endometrial surface to the other (Fig. 2-18). In addition, transvaginal sonography is used initially to detect congenital uterine anomalies that cause infertility or early spontaneous abortion. Thereafter, MR imaging is used to characterize and evaluate mÃ¼llerian anomalies. A complete description of these anomalies is found in Incidence and Classification.

In women with complex anomalies associated with vaginal agenesis or imperforate hymen, hematocolpos is commonly seen, often with associated hematometra or hematosalpinx (Hall, 1994). A complete duplication anomaly, such as uterus didelphys, can be accurately diagnosed by sonography with the imaging of two separate and divergent uterine horns that have a deep fundal cleft between the two hemi-uteri and a wide angle between the two endometrial cavities (Fig. 2-19). The differentiation between a bicornuate and septate uterine anomaly is less confidently achieved by traditional transvaginal sonographic techniques. Ideally, measurement of the angle between the two endometrial cavities and analysis of the fundal shape helps to differentiate between a bicornuate uterus (angle ≥ 105Â°) and a septate uterus (angle ≤ 75Â°) (Reuter, 1989). Combining TVS findings with SIS provides accuracy up to 90 percent to distinguish the two anomalies. Three-dimensional sonography is considered by some to be the best noninvasive method for distinguishing between these uterine anomalies (Kupesic, 2001).

FIGURE 2-19

Uterus didelphys. Transvaginal sonogram in the transverse plane best depicts the two completely separate uterine horns. A gestational sac is evident in the right uterus. *(Courtesy of Dr. Elysia Moschos.)*

A unicornuate uterus, however, is difficult to recognize sonographically. The dilated rudimentary horn is often misdiagnosed as a uterine or adnexal mass (Hall, 1994). Complete evaluation of these cases requires MR imaging. With any uterine anomaly, especially if unilateral, proper positioning of the kidneys should be documented because of increased associated genitourinary anomalies.

Pelvic endometriosis is another frequent cause of infertility. Sonography is the most common imaging procedure to evaluate suspected endometriosis, although its role is mostly limited to evaluation of endometriotic cysts. Its capability in the detecting small implants and adhesions is limited. Endometriomas exhibit a variety of sonographic appearances, the most common being a cystic pelvic mass with a thick wall and an internal structure made of diffuse low-level echoes (see Fig. 10-5). Magnetic resonance imaging has been proven to be more specific than sonography for identifying endometriomas, and thus it is indicated in difficult cases (see Fig. 10-6).

One of the most powerful uses of sonography in the infertile patient is surveillance of various treatment techniques. Sonography is used to monitor folliculogenesis both in normal and stimulated cycles. In natural cycles, observation of a developing follicle and prediction of ovulation allow optimal timing of procedures such as post coital testing, human chorionic gonadotropin (hCG) administration, intercourse, insemination, and ovum collection. At ovulation, the follicle usually disappears and fluid is observed in the cul-de-sac of Douglas. At the follicular site, the corpus luteum appears as an irregular structure containing a small quantity of fluid, internal echoes, and a thick wall (Dill-Macky, 2000). In stimulated cycles, sonographic detection of too many follicles allows withholding hCG induction to prevent ovarian hyperstimulation syndrome. If this develops, sonography is used to grade disease severity through measurements of ovarian size, detection of ascites, and analysis of renal flow resistances (Fig. 20-5). (Barnhart, 2000; Parsons, 2001). Blood flow in the ovulating ovary decreases throughout the menstrual cycle. At ovulation, there is a dramatic increase of blood flow velocities in vessels surrounding the corpus luteum because of angiogenesis with low-impedance waveforms. In women undergoing in vitro fertilization, low ovarian vessel impedance may correlate directly with pregnancy rates (Baber, 1988). Lastly, sonography can be used to guide interventional maneuvers such as oocyte retrieval and transfer of embryos into the endometrial cavity (Fig. 20-12).

Sonosalpingography

Until recently, a fallopian tube could be detected with sonography only when distended by fluid, such as in cases of obstruction. Injection of echogenic contrast material under real-time sonography, called *sonosalpingography* or *sonohysterosalpingography* , is proposed as a means to assess tubal patency without the need for HSG. It can be performed in an outpatient setting, has good patient acceptance, and it is almost as accurate as HSG (Campbell, 1994; Lerner, 1997).

Sonosalpingography is done in a manner similar to SIS. Fluid egress from the uterine cavity is blocked by a balloon catheter within the cervical canal. The approximate location of the fallopian tubes as they insert into the uterine cornua is identified with the transvaginal probe. Tubal patency is confirmed by visualizing passage of saline through the tubes, which is detected by means of color or pulsed Doppler techniques (Kupesic, 1997). A 90-percent correlation with traditional techniques has been reported by many (Allahbadia, 1992; Campbell, 1994; Schlief, 1991; Stern, 1992).

However, a patent tube does not always correlate with a normally functioning tube. Thus, HSG may still be needed for more accurate delineation of the tubal anatomy for selected indications.

Three-Dimensional Sonography

Sonogram images shown on a monitor screen are two-dimensional (2-D). Anatomic parts, however, are inherently three-dimensional (3-D). New scanners allow collection of 3-D data and represent it on a two-dimensional screen (Kurjak, 2001). Thus, 3-D techniques overcome the limitations of conventional 2-D sonography by allowing a more detailed assessment of morphology, with no restriction of number and orientation of scanning planes (Aruh, 1997; Umek, 2002).

Three-dimensional sonography has recently been used in clinical practice, especially obstetrics. In gynecology, it is useful in the assessment of complex ovarian masses, uterine anomalies, evaluation of the uterine cavity, and diagnosis of interstitial pregnancies (Fig. 2-20) (Izquierdo, 2003).

FIGURE 2-20

There have been variable results concerning the role of 3-D transvaginal sonography with respect to its sensitivity and specificity in detecting malignancies in adnexal masses (Alcazar, 2003). There is agreement that 3-D sonography allows a more detailed assessment of the internal structure of ovarian masses. Moreover, the addition of color Doppler to 3-D evaluation allows display of the internal architecture of neovascularization, also characteristic of malignant neoplasms (Kurjak, 2001).

A number of investigators have described 3-D sonography with image reconstruction for evaluation of congenital mÃ¼llerian anomalies (Jurkovic, 1995; Raga, 1996; Steiner, 1994). It provides detailed images of both the internal shape of the endometrial cavity as well as the external contour of the fundus. Thus, various types of mÃ¼llerian anomalies can be differentiated because the uterine horns and fundal contour can be displayed clearly in the same plane. Importantly, the information obtained from 3-D imaging can provide helpful details for preoperative planning and may even help predict the likely outcome of metroplasty (Wu, 1993).

Using 3-D technology, it is possible to generate endometrial cavity images that allow better definition and characterization of focal endometrial thickenings, such as polyps, hyperplasia, and cancer. In their comparative study of 36 women with postmenopausal bleeding, Bonilla-Musoles and associates (1997) compared results from 3-D SIS with findings from TVS, transvaginal SIS, transvaginal color Doppler, and hysteroscopy. Visualization of the uterine cavity and endometrial thickness with 3-D SIS was comparable to hysteroscopy and better than with the other sonographic techniques.

Compression Sonography of Lower Extremities

Compression sonography, often combined with color Doppler sonography, is the initial test currently used to detect deep venous thrombosis (see Fig. 39-4) (Greer, 2003). Sonographic evaluation of leg veins is divided into three parts: (1) the groin and thigh are examined with the patient supine; (2) the popliteal region is examined with the patient lying on her side or sitting; and finally, (3) the calf veins are examined with the patient sitting. The diagnosis of thrombosis is based on impaired visibility, noncompressibility, and typical echo pattern of a thrombosed vein (Fig. 2-21). In symptomatic patients, examination of the femoral, popliteal, and calf trifurcation veins is more than 90-percent sensitive and over 99-percent specific for proximal thrombosis (Davis, 2001; Schellong, 2004). It has a negative predictive value of 98 percent (American College of Obstetricians and Gynecologists, 2000a, 2000b). Although useful for proximal occlusions, compression sonography is significantly less reliable for detecting calf vein thromboses (Bates, 2004).

Lensing and colleagues (1989) compared contrast venography with real-time sonography in 220 patients. They found that both the common femoral and popliteal veins were fully compressibleâ€”no thrombosisâ€”in 142 of 143 patients who had a normal venogram (99-percent specific). All 66 patients with proximal vein thrombosis had noncompressible femoral or popliteal veins, or both (100-percent sensitive). Importantly, normal venous sonography findings do not necessarily exclude pulmonary embolism because the thrombosis may have already embolized or because it arose from deep pelvic veins inaccessible to sonographic evaluation (Goldhaber, 2004).

RADIOGRAPHY

Plain radiographs are used in gynecologic practice in a manner similar to other medical specialties. Plain films include radiographs of the chest and abdomen. Some plain radiographs are used to evaluate women with gynecologic malignancies (Soper, 2001). Examples are chest radiographs to screen for pulmonary metastases during malignancy staging, including gestational trophoblastic disease, and for surveillance after initial treatment. A number of specialized radiographic procedures are especially useful or are specific to evaluation of gynecologic conditions.

Intravenous Pyelography

Excretory urography, or intravenous pyelography (IVP), is a radiographic study which provides imaging of the urinary tract. Comparing CT and sonography, CT images show more detail of pelvicalyceal and ureteric anatomy, but provides less information

about the renal parenchyma and bladder (Webb, 2001).

After an initial plain radiograph, termed a scout film, delineates urinary calculi, intravenous contrast agent is given. Immediately thereafter, the concentrating function of the proximal tubules renders the renal parenchyma radiodenseâ€”in the nephrogram phaseâ€”and allows evaluation of renal size, contour, and axis. A radiograph obtained after 5 minutes depicts contrast excreted into the collecting systemâ€—the pyelogram phaseâ€—and the collecting system is evaluated for symmetry and promptness of excretion. A final postvoiding radiograph completes the evaluation.

Many preoperative pyelograms performed in the past have been supplemented by sonography and spiral CT imaging. For example, most clinicians in the United States have substituted CT imaging in cervical cancer staging because it allows visualization of the cervix, parametria, uterus, adnexa, retroperitoneal lymph nodes, liver, and ureters (International Federation of Gynecology and Obstetrics [FIGO] Committee on Gynecologic Oncology, 1998). However, a preoperative IVP is often used for suspected urinary anomalies in women with a reproductive tract anomaly. It is also indicated to confirm lower urinary tract patency in the setting of pelvic neoplasm, such as a large cervical or pelvic mass that is fixed and adherent to the pelvic side wall or that causes urinary symptoms.

As many as 5 to 10 percent of women have an allergic reaction to iodide during IVP, and 1 to 2 percent of these reactions is life-threatening. Pretreatment with oral corticosteroids has significantly reduced the incidence of allergic reactions (Lasser, 1987). Moreover, nonionic iodinated contrast media agents have a 5- to 30-fold decreased incidence of allergic reactions, but are more expensive than traditional ionic contrast media (Mishell, 1997).

There also may be significant nephrotoxicity due to hyperosmolar ionic contrast, which is believed to cause direct tubular insult and ischemic injury. Women with diabetes, renal impairment, and congestive heart failure are at high risk for contrast nephrotoxicity. Thus, low osmotic, nonionic contrast materials are less nephrotoxic and should be considered in special cases such as these (Mishell, 1997).

Voiding Cystourethrography and Positive Pressure Urethrography

These radiographic procedures are commonly used imaging methods to evaluate the female urethra and are discussed in detail in Chapter 26, Voiding Cystourethrogram. In addition, recent studies have demonstrated that MR imaging is an excellent modality for visualizing urethral diverticula and that it is more sensitive than voiding cystourethrography for delineating diverticula with complex structures (Neitlich, 1998; Daneshgari, 1999).

Hysterosalpingography

This radiographic imaging technique is used to evaluate the endocervical canal, endometrial cavity, and the lumina and patency of the fallopian tubes by injecting radiopaque contrast material through the cervical canal (see Chap. 19, Hysterosalpingography). Used primarily in evaluation of infertility, an average HSG is performed in 10 minutes, involves approximately 90 seconds of fluoroscopic time, and has an average radiation exposure to the ovaries of 1 to 2 rads.

Hysterosalpingography is performed between cycle days 5 and 10, following cessation of menstrual flow to minimize infection and the risk of flushing an ovum from the fallopian tube. The test causes cramping and a nonsteroidal anti-inflammatory drug taken 30 minutes prior to the procedure may minimize discomfort. An acorn cannula, pediatric Foley catheter, or designated injection catheter is introduced just inside the external cervical os and contrast media is injected. A paracervical block may be indicated in selected patients, such as those with cervical stenosis. Because rapid injection may cause tubal spasm, a slow injection of usually no more than 3 to 4 mL of media allows a clear outline of the uterine cavity. Generally, only three radiographic views are neededâ€—a preliminary view before injecting contrast, a view showing fill of the uterine cavity, and a third demonstrating spill of contrast from the tubes into the peritoneal cavity.

There are many variations in the appearance of a normal HSG (see Fig. 19-5). The endometrial cavity is usually triangular or sometimes T-shaped in the anteroposterior projection. In the lateral view it is oblong. The contour of the endometrium is usually smooth. It occasionally appears to have polypoid-filling defects that can be isolated or diffuse, and can be difficult to distinguish from endometrial polyps or hyperplasia (Lindheim, 2003a). Inadvertent injection of air bubbles introduces artifact.

Contraindications to HSG include acute pelvic infection, active uterine bleeding, pregnancy, and iodine allergy. Complications of HSG are rare but can be serious. The overall risk of acute pelvic infection serious enough to require hospitalization is less than 1 percent, but may be up to 3 percent in women with prior pelvic infection (Stumpf, 1980). Because of serious morbidity, routine prophylaxis is given with doxycycline orally, 100 mg twice daily, beginning the day before HSG and continued for 2 more days thereafter. In addition, pelvic pain, uterine perforation, and vasovagal reactions may occur. Complications from the contrast include allergic reactions and entry into the vascular system with high injection pressures. Embolic phenomena, pelvic peritonitis, and granuloma formation with oil-based contrast agents are rare.

Selective Salpingography

In some cases, it is not possible to distinguish whether a tubal blockage seen by HSG is caused by anatomic occlusion or tubal spasm. Hysteroscopic tubal cannulation can further clarify and treat many cases of proximal tubal occlusion as described in Hysteroscopic Proximal Fallopian Tube Cannulation. Alternatively, transcervical selective salpingography and tubal catheterization (SS-TC) under fluoroscopic guidance is another procedure that may be used. It is performed during the follicular phase of the cycle with the catheter forwarded through the cervix and advanced by tactile sensation to the tubal ostium. The position of the catheter is checked fluoroscopically and if satisfactory, water- or oil-soluble contrast is injected. If the obstruction is overcome, the tubal contour is outlined with contrast agent. If the proximal tubal obstruction persists, a guidewire is threaded through the inner cannula of the catheter and advanced toward the obstruction and gently manipulated to overcome the blockage. The guidewire is then withdrawn, and contrast medium is injected through the catheter to confirm patency. This fluoroscopic tool is effective at diagnosing and treating proximal tubal blockage (Capitanio, 1991; Ferraiolo, 1995; Thurmond, 1991; Woolcott, 1997).

Bone Densitometry

Depending on its mineral density, bone absorbs x-rays to different degrees. Although plain radiography is useful in the initial evaluation of osteopenia and osteoporosis, it is not sensitive enough to assess bone density. Other techniques are accurate, sensitive, and safe to quantify severity of bone loss and serve as a baseline for evaluating therapeutic benefits (Kaplan, 1995). Most measurements of bone density provide site-specific information about the time-specific quantity of bone, but do not assess either current or past rates of bone remodeling. Sequential density measurements are therefore necessary to assess the rate of bone loss (Kaplan, 1995).

Currently, two methods used commonly are dual-energy x-ray absorptiometry (DEXA) to assess integral bone mineralâ€”cortical and trabecularâ€”density in the hip and spine, and quantitative computed tomography (QCT) to evaluate bone mineral in high-turnover trabecular bone.

Of these, DEXA is the best technique for assessment of axial osteopenia (see Fig. 21-10). It employs two x-ray beams of different energy levels and accurately measures bone density in the hip and spineâ€”areas most vulnerable to osteoporotic fractures. The spine is commonly scanned between the first and fourth lumbar vertebrae Measurements with DEXA are precise and accurate, radiation dose is lowâ€”less than 5 mrem, and patient acceptability is high because the procedure time is usually only 5 to 15 minutes (Jergas, 1993). Although DEXA instruments that measure bone mass at peripheral sites such as in the forearm are also available, these may not predict hip fractures as accurately as direct hip measurement. One disadvantage of DEXA is that bone spurs, aortic calcifications, and arthritis may falsely elevate reported bone density.

In contrast, QCT uses either x-rays or gamma rays to provide a cross-sectional view of the vertebral body. As the rate of turnover in trabecular bone is nearly eight times that in cortical bone, this technique detects early metabolic changes in a highly vulnerable region. Its precision is excellent but may be reduced with severe osteopenia and kyphosis, with increased fat content from obesity or fatty bone marrow in older patients, and by the technical aspects of positioning (Kaplan, 1995; Miller, 1999).

Another technique, which has not been validated, is quantitative sonography (Pejovic, 1999). This may provide information about the structural organization of bone (World Health Organization [WHO] Study Group, 1994; American Association of Endocrinologists, 1996). Small portable ultrasound units are available for rapid measurement of heel bone mass in the office, with readings made in 10 seconds.

Uterine Artery Embolization

This is a definitive independent treatment of uterine leiomyomas that was first introduced in the early 1990s. Uterine artery embolization (UAE) is a radiologic procedure that uses angiography to visualize blood circulation and is discussed fully in Chapter 9, Uterine Artery Embolization. Primarily, flow through the uterine arteries is stopped, resulting in leiomyoma ischemia and necrosis.

COMPUTED TOMOGRAPHY

This procedure involves multiple exposures of thin x-ray beams, which are translated into two-dimensional axial images of the particular area of interest, termed a *slice* . Multiple slices of the target body part are obtained along its length. Multiple-channel helical computed tomography, also called spiral CT, allows for continuous acquisition of images in a spiral with the potential for image reformatting in multiple planes. This technique is much faster and allows for images to be manipulated for analysis after they have been acquired.

Many variables affect radiation dose, especially slice thickness and number of cuts obtained. If a study is performed with contrast, twice as many images will be obtained, and the target area radiation dose is therefore doubled.

Normal Anatomy with Computed Tomography

The uterus is identified as a homogenous, soft tissue oval or triangular structure situated posterior to the bladder (Fig. 2-22). The uterine walls enhance after intravenous contrast medium. Unlike sonography and MR imaging, the endometrium is not identifiable on CT imaging. The smooth lateral margins of the cervix are well defined because of contrast with adjacent parametrial fat. There is uniform enhancement of the cervix after intravenous contrast medium. The endocervical canal, which can be identified by MR imaging, cannot be distinguished by CT imaging. Images of the vagina and vulva are strongly enhanced by contrast medium (Constant, 1989). Typically, the ovaries are relatively hypodense, variable in appearance and position, and usually situated posterolateral to the uterus (Friedman, 1992).

The parametria can be well visualized with CT imaging, and thus it is useful for gynecologic malignancies. The parametria consist of a large proportion of fatty tissue, but contain some soft tissue representing fibrous tissue, blood vessels, and lymphatics. The cardinal ligaments are seen on axial scans as triangular structures of soft tissue extending from the lateral borders of the cervix and upper vagina to fuse with the deep fascia covering the levator ani. The round ligaments can be identified in the upper margin of the parametria, extending anterolaterally toward the inguinal ring (Friedman, 1992). The uterosacral ligaments are easily identified on axial and coronal views, passing from the lateral margins of the cervix and vaginal fornices to the sacrum. Finally, the ureter and the uterine arteries can be identified within the broad ligament (Constant, 1989).

Gynecologic Malignancy

In most instances, sonography is the preferred initial method of evaluating the female pelvis (Fleischer, 1989; O'Brien, 1984). With pelvic pathology, MR imaging is now often preferable to CT imaging because it does not use radiation and provides excellent views of pelvic structures in multiple planes (Carr, 2002). For these reasons, there is a relative paucity of literature concerning CT images of benign pelvic disorders.

However, CT imaging is probably the most frequently used imaging technique for the evaluation and surveillance of gynecologic malignancies (Soper, 2001). Oral and rectal contrast allows visualization of the gastrointestinal tract, whereas intravenous contrast enhances visualization of blood vessels and viscera. Rapid resolution CT imaging have much greater sensitivity than techniques used previously and can be used to detect 2- to 3-mm lesions in the lungs and solid viscera (see Fig. 37-8). Scans with contrast yield high-quality information about retroperitoneal lymph nodes and ureters. Spiral CT scans record images during arterial, capillary, and venous phases of tissue enhancement during contrast administration. This allows improved imaging of small vessels and tissue interfaces within the visceral parenchyma. Whereas sensitivity for small intraperitoneal metastases is limited, CT scans can give a useful estimate of the location of bulky metastases, such as in women with advanced ovarian cancer (see Fig. 35-8). Disadvantages include radiation exposure, artifacts created by metallic clips or prosthetic joints, and complications related to iodinated intravenous contrast material (Soper, 2001).

POSITRON EMISSION TOMOGRAPHY IMAGING

This technique is based on the use of short-lived radiotracers. Positron emission tomography (PET) has become a vital clinical tool, particularly for cancer diagnosis and management. It takes advantage of the ability of various radiochemical compounds to serve as tracers for measuring specific metabolic processes suggestive of malignancy or infection (Juweid, 2006). This enables detection of the early biochemical anomalies of cancer that precede the structural changes displayed by other imaging techniques.

The most common PET radiochemical tracer used in clinical practice is 2-[18F]-fluoro-2-deoxy-D glucose (FDG). This tracer is used to localize areas of accelerated rates of glycolysis commonly found in neoplastic cells (Goh, 2003).

The FDG-PET scan is currently being evaluated for initial imaging in women with cervical cancer (Rose, 1999). In some cases, PET scanning detects unsuspected nodal or distant metastases in women with cervical cancer more often than CT imaging. In addition, FDG-PET scanning is also being used in the surveillance of patients with ovarian cancer and has been shown to roughly correlate with findings at second-look surgery in patients who are in clinical remission (Fig. 2-23) (SchrÃ¶der, 1999).

MAGNETIC RESONANCE IMAGING

With this technology, images are constructed based on the radiofrequency signal emitted by hydrogen nuclei after they have been "excited" by radiofrequency pulses in the presence of a strong magnetic field. The radiofrequency signal emitted has characteristics called *relaxation times* . These include the T1-relaxation time (longitudinal) and the T2-relaxation time (transverse).

In a magnetic field, protons will align themselves in the same direction as the field running through the bore of the magnet. If a radiofrequency pulse is applied, these protons are forced out of alignment and rotate in phase with one another. The T1-relaxation is the time it takes for protons to realign with the magnetic field after a radiofrequency pulse is applied. T2-relaxation is the time it takes for the protons to diphase from each other after a radiofrequency pulse is applied.

Because these properties vary among tissues, they are the factors principally responsible for contrast among tissues. The signal intensity of one tissue compared with another, or contrast, can be manipulated by varying the elapsed time between applications of radiofrequency pulses, which is called *repetition time* . Further manipulation of the time between a radiofrequency pulse and sampling the emitted signal is called the *echo delay time* . Sequences with a short repetition time and short echo delay time are called *T1-weighted* and sequences with a long repetition time and long echo delay time are regarded as *T2-weighted* . As examples, the hydrogen molecules in a water-containing area, such as urine in the bladder, have longer relaxation times than those in a solid tissue such as liver. On T1-weighted images, urine in the bladder will appear dark or low signal intensity. On T2-weighted images the same urine will appear bright or high-signal intensity. The strength of the magnetic field within the bore of the magnet is

measured in tesla (T) (1 tesla = 10,000 gauss).

Technique

Standard imaging technique includes both T1- and T2-weighted sequences, acquired in two planes, usually axial and sagittal. The T1-weighted sequence most clearly delineates organ boundaries with surrounding fat, allows optimal visualization of lymph nodes, and is necessary for tissue and fluid characterization such as hemorrhagic or fat-containing lesions (Nurenberg, 1995). The T2-weighted sequence provides detailed definition of internal organ architecture, such as the zonal anatomy of the uterus and vagina, and aids identification of normal ovaries. T2-weighted images are usually superior in depicting pathologic conditions of the uterus and ovaries.

Some MR images have better resolution when a paramagnetic contrast agent such as gadolinium-DTPA is given. For example, it is routinely used for evaluation of endometrial and ovarian carcinoma. Magnetic resonance contrast agents change the local magnetic field in tissues under study. Normal and abnormal tissues react differently to the contrast, and these differences can be displayed. Concentrations and dosages of MR contrast agents are significantly lower than those used in CT imaging. Side effects are rare, and they can be used even if there is a history of allergy to other contrast agents. They undergo renal excretion within 24 hours and are extremely safe for patients with compromised renal function. During pregnancy, however, paramagnetic contrast agents should be given only if the potential benefits outweigh the potential fetal risk demonstrated in animal studies (American College of Obstetricians and Gynecologists, 2004). Gadolinium-DTPA is the only contrast material approved for MR imaging in the United States.

The multiplanar capability of MR imaging allows a study to be individualized to a specific clinical question. The transverse plane of imaging is routinely acquired in all cases, with additional sequences obtained in either the sagittal or coronal plane. The sagittal plane optimizes visualization of the uterus, whereas the coronal plane is preferred for evaluation of the ovaries.

Safety

There have been three major areas examined concerning the potential effect of MR imaging at field strengths used clinically, that is, those less than 2 tesla. These areas include the effects from static magnetic fields and gradient magnetic fields. To date, there are no reported harmful effects from MR imaging, including any mutagenic effects (American College of Radiology, 1998; International Commission on Non-ionizing Radiation Protection, 2003; Wagner, 1997).

Some, but not all, devices preclude MR imaging. For example, women with intrauterine devices can be safely imaged. Contraindications, however, include mechanically, electrically, or magnetically activated implants or devices such as internal cardiac pacemakers, neurostimulators, implantable cardiac defibrillators, implantable electronic infusion pumps, and cochlear implants. Certain intracranial aneurysm clips and any metallic foreign body in the globe of the eye contraindicate scanning (Cunningham, 2005a).

Use in Gynecology

Although sonography is preferred for initial evaluation of suspected gynecologic disease, in some cases, more detail is needed. Multiplanar imaging, superior soft tissue contrast, and large field of view offer distinct advantages of MR imaging to assess gynecologic abnormalities (Leung, 2000). For example, a major use of MR imaging is staging pelvic malignancies. Additionally, MR imaging is preferable for surveillance in women with cancer because it does not employ ionizing radiation.

MR imaging is often used when sonographic findings are equivocal. Common indications include distorted pelvic anatomy, large masses that may be difficult to delineate with sonography, suspected adenomyosis, and some endometrial disorders (Javitt, 2005).

Normal Findings

The pelvic organs are generally moderate to low signal intensity on T1-weighted images. T2-weighted images of the menstruating uterus (Fig. 2-24) depict a high signal intensity endometrium, contiguous low signal intensity inner myometrium which is the junctional zone, and a moderate signal intensity outer myometrium (McCarthy, 1986). The cervix can be distinguished from the body of the uterus by its prominent fibrous stroma which has an overall lower signal intensity. The internal architecture of the cervix is seen on T2-weighted images as central high signal intensity (endocervical glands and mucus) surrounded by low signal

intensity (fibrous stroma) and peripheral moderate signal intensity (smooth muscle intermixed with fibrous stroma) (Lee, 1985). T2-weighted images of the vagina depict central high-signal mucosa and mucus that is surrounded by a low signal intensity muscular wall (Hricak, 1988a). Ovaries are normally seen on the T2-weighted sequence as moderately high signal intensity stroma containing very high signal intensity follicles (Dooms, 1986). The fallopian tubes are not typically visualized. Hormonal status influences the MR appearance of all structures and reflects associated physiologic changes.

Magnetic Resonance Imaging in Gynecology

UTERUS

Leiomyomas

Magnetic resonance imaging is the most accurate tool for evaluation of leiomyomas (Ascher, 2003). Although TVS remains the initial imaging technique for evaluating women with suspected leiomyomas, there is a false-negative rate of up to 20 percent (Gross, 1983). This is due in part to its limited field of view, decreased image resolution with increasing patient body fat, and distorted anatomy because of large or multiple leiomyomas. Leiomyomas less than 2 cm are routinely not identified during TVS even when symptomatic. There are also instances in which thorough imaging is warranted, for example prior to uterine artery embolization (UAE) or hysteroscopic resection. Also, MR imaging is used when TVS is equivocal or nondiagnostic (Ascher, 2003). In addition, the effects of GnRH-agonist therapy to shrink leiomyoma volume can be quantified with MR imaging (Lubich, 1991).

As shown in Figure 2-25, leiomyomas have a specific MR appearance and thus can be differentiated from adenomyosis or adenomyoma with 90-percent accuracy (Mark, 1987; Togashi, 1989). This is important when myomectomy is considered. Leiomyomas as small as 0.5 cm are best seen on T2-weighted images and appear as round, sharply marginated, low signal intensity masses relative to the myometrium (Hricak, 1986). Multiplanar views allow for accurate localization as subserosal, intramural, or submucosal. The stalk of a prolapsed submucosal leiomyoma can be reliably identified with MR imaging and confirm its accessibility to hysteroscopic resection. Intramural or subserosal leiomyomas are frequently circumscribed by a high signal intensity rim which represents edema from dilated lymphatics and veins. Tumors larger than 3 cm often are heterogeneous because of varying degrees and types of degeneration (Hricak, 1986; Yamashita, 1993).

FIGURE 2-25

The endometrium is identified as the bright, high-signal-intensity line anterior to the leiomyomas (**arrow**). *(Courtesy of Dr. Diane Twickler.)*

Enhancement of leiomyomas with intravenous gadolinium contrast may be predictive of successful response to uterine artery embolism. Hypervascularity, which is seen as a bright signal on T2-weighted images after intravenous gadolinium, correlates with a good response to UAE (Jha, 2000). In contrast, leiomyomas with negligible enhancement and high signal intensity on T1-weighted sequences do not respond to UAE. Contrast MR imaging is also useful for monitoring tumor response after UAE. Successfully embolized leiomyomas demonstrate a decrease in size and no enhancement with contrast, consistent with degeneration (DeSousa, 1999).

Magnetic resonance imaging guidance of focused ultrasound therapy (MR imaging-FUS) has been used to treat symptomatic leiomyomas (Cline, 1992). Without MR guidance, focused ultrasound therapy is hampered by difficulty in precise targeting of the

beam and in receiving feedback regarding thermal damage created. Fortunately, excellent soft-tissue resolution with MR imaging enables accurate tissue targeting. Moreover, magnetic resonance imaging parameters have an intrinsic sensitivity to temperature. Thus, MR imaging can measure accurate, near real-time thermometry, and thermal damage created by focused ultrasound can be assessed immediately (Hindley, 2004). A series of high-power ultrasound pulsesâ€"sonicationsâ€"are directed into the leiomyoma, and power is adjusted until an adequate temperature and thermal dose is reached. Pulse duration is generally about 15 seconds, and the interval between pulses, 3 minutes, allows tissues to cool between treatments. The average procedure duration is about 3.5 hours (Hindley, 2004).

Preliminary studies indicate that MR imaging-FUS therapy is a safe and feasible minimally invasive alternative for leiomyoma treatment (Chen, 2005; Stewart, 2003). It may provide short-term symptom relief with the advantage of a quicker recovery and few major adverse events. However, little information is available on costs and long-term results compared with other treatments such as UAE and surgery.

Adenomyosis

To diagnose adenomyosis, MR imaging has been shown to be equivalent or superior to sonography, with a sensitivity of 88 to 93 percent and a specificity of 66 to 91 percent (Ascher, 1994; Reinhold, 1996). Its contrast to the sharply demarcated, homogeneous MR-imaging appearance of leiomyomas is shown in Figure 2-26. Areas of adenomyosis contain internal punctate foci of increased signal on both T1- and T2-weighted images, and they are oval-shaped with ill-defined margins (Togashi, 1988, 1989). The highly signal intense foci represent ectopic endometrium and cystically dilated endometrial glands, with or without hemorrhage (Reinhold, 1996). Diffuse areas of adenomyosis will be evident by thickening greater than 11 mm of the low signal intensity junctional zone, that is, the inner myometrium, and linear high signal intensity striations radiating out from the endometrial surface. These striations are thought to represent direct invasion of the endometrial zona basalis into the underlying myometrium. Contrast administration does not increase the diagnostic accuracy for adenomyosis (Outwater, 1998).

Congenital Anomalies

MÃ¼llerian duct anomalies comprise a spectrum of developmental malformations associated with varying degrees of adverse reproductive outcomes. They are traditionally diagnosed using sonography and hysterosalpingography with or without saline infusion. Until recently, further evaluation required laparoscopy, laparotomy, or hysteroscopy. These invasive techniques have now largely been replaced by MR imaging (Troiano, 2003). It is the preferred procedure for evaluating mÃ¼llerian duct anomalies and has an accuracy of up to 100 percent (Carrington, 1990; Doyle, 1992; Fedele, 1989; Fielding, 1996; Pellerito, 1992a).

One example of MR imaging superiority is differentiation of septate and bicornuate uteri, which is imperative with regard to their clinical implications and surgical treatment. In a bicornuate uterus, the dividing septum is composed of myometrium, and with MR imaging it is characterized by signal intensity of myometrium. The endometrium of a bicornuate uterus has a normal width and lines two uterine cavities that communicate, as demonstrated by their confluent increased signal intensity (Carrington, 1990; Fedele, 1989; Pellerito, 1992a). The contour of the fundus is concave. Finally, the bicornuate uterus typically has a significant notchâ€"larger than 1 cmâ€"in the fundus between the two horns, and the intercornual diameter is greater than 4 cm (Carrington, 1990; Fedele, 1989; Pellerito, 1992a).

The septate uterus is a result of incomplete resorption of the final fibrous septum between the two uterine horns. It is composed of collagen which has low signal intensity on both T1- and T2-weighted images (Fig. 2-27). The fundal contour of the septate uterus can be convex, flattened, or mildly concave, but the fundal indentationâ€"the notchâ€"is less than 1 cm (Leung, 2000). Also in contrast to the bicornuate uterus, the intercornual diameter of the septate uterus is not increased, and thus each uterine cavity is smaller than usual (Carrington, 1990; Forstner, 1994).

Other anomalies for which MR imaging is used include uterine didelphys and unicornuate uterus with its rudimentary horn (Fig. 2-28). It can also determine whether endometrium is contained within the rudimentary horn and whether the horn communicates with the main uterine cavity, a finding of considerable clinical importance (see Chap. 18, Unicornuate Uterus) (Leung, 2000). The superior resolution of MR imaging is also important for planning surgical treatment of cloacal anomalies (Nurenberg, 1995; Pena, 1990).

ADNEXAL MASSES

Sonography is the imaging modality of choice for initial evaluation of adnexal masses, whereas MR imaging is useful in some cases in which sonography is inconclusive. Magnetic resonance imaging frequently can further characterize lesions, for example differentiate adnexal from uterine masses. It has higher accuracy to diagnose specific adnexal lesions compared with sonography: 60 to 95 percent versus 53 to 88 percent (Leung, 2000; Smith, 1988; Stevens, 1991; Thurnher, 1990).

GYNECOLOGIC MALIGNANCY

Cervical Cancer

Although not used for screening, MR imaging is excellent for preoperative staging of gynecologic neoplasms. Its superior soft-tissue contrast resolution and ability to image directly in multiple planes allows evaluation of lymphadenopathy and local tumor extension.

Although CT imaging remains the standard of care for the assessment of nodal disease and distant metastases, MR imaging consistently outperforms clinical and CT staging for cervical cancer in the assessment of local tumor extension. Studies of preoperative MR imaging evaluation have shown it to be both cost-effective and therapeutically valuable (Durfee, 2000; Hricak, 1996). Current recommendations for MR imaging with cervical cancer include tumor with a transverse diameter >2 cm by physical examination, endocervical or predominately infiltrative tumors that cannot be accurately assessed clinically, and women who are pregnant or have concomitant uterine lesions, such as leiomyomas, that make assessment difficult (Ascher, 2001). When parametrial and sidewall invasion are difficult to assess clinically, MR imaging may play an important role in their evaluation

(Ascher, 2001). It has a 95-percent negative-predictive value for parametrial invasion, allowing the absence of parametrial invasion to be determined with confidence (Hricak, 1988b; Lien, 1991; Subak, 1995).

Endometrial Cancer

Surgery is currently the most accurate staging method. For the same advantages cited for cervical cancer, MR imaging has recently been gaining acceptance to evaluate endometrial carcinoma (Ascher, 2001). Knowledge of the degree of myometrial and cervical extension affects the type of hysterectomy selected, lymph node dissection, and decision to use preoperative intracavitary radiation (Boronow, 1984; Frei, 2000; Larson, 1996). Therefore, MR imaging is recommended if there is a high probability for lymph node metastases, that is, high-grade tumor, papillary or clear cell histology, or cervical invasion, or if there is a need for multifactorial assessment of myometrial, cervical, and lymph node involvement (Ascher, 2001).

Ovarian Cancer

Magnetic resonance imaging for ovarian neoplasms is reserved for evaluation when transvaginal sonography is indeterminate or nondiagnostic (Nurenberg, 1995). Magnetic resonance imaging is particularly useful to assess the origin of an adnexal massâ€"uterine, ovarian, or nongynecologicâ€"and if ovarian in origin, determining whether the mass is neoplastic versus non-neoplastic and malignant versus benign (Ascher, 2001).

Sensitivity of MR imaging for detecting adnexal pathology ranges from 87 to 100 percent and is therefore similar to that of sonography and CT (Siegelman, 1999). The accuracy of MR imaging ranges from 83 to 95 percent to characterize an ovarian mass as benign or malignant, compared with 53 to 88 percent with sonography and 66 to 94 percent for CT (Komatsu, 1996; Stevens, 1991; Yamashita, 1995). In a large prospective trial to evaluate ovarian masses detected with transvaginal sonography, MR imaging was more accurate than CT or Doppler sonography for diagnosing malignancy (Kurtz, 1999). It is also more accurate than CT for detecting extrapelvic peritoneal metastases and identifying omentum, bowel, and osseous and vascular structures (Low, 1995). Finally it can be used to evaluate non-resectability (Forstner, 1995).

MR evaluation of an adnexal mass should include gadolinium-enhanced images to assess tumor vascularity and fat- saturation techniques to differentiate blood from fat on T1-weighted high signal intensity lesions (Ascher, 2001). Although histology cannot be diagnosed, findings that are suspicious for malignancy include enhancing solid components, thick septations, nodules, and papillary projections.

UROGYNECOLOGY

Very fast-sequence MR imaging, termed *dynamic imaging* , allows detailed delineation of pelvic structures in women with stress urinary incontinence or prolapse of the bladder, uterus, or rectum. Grading systems of pelvic organ prolapse and pelvic floor relaxation based on dynamic imaging have been developed by Barbaric and colleagues (2001). Other imaging techniques have also been developed for evaluation of prolapse (Fielding, 1998). These include placement of various contrast materials, for example, lubricating gel or sonographic transmission gel, into the vagina and rectum to assess vaginal vault prolapse and rectocele, as well as a suitable replacement for defecography to evaluate prolapse (see Chap. 25, Evacuation Proctography). (Kelvin, 2000; Lienemann, 1997; Schoenenberger, 1998). Most recently, MR imaging with 3-D reconstruction has been used to describe levator muscle morphometry in term pregnant nulliparous women to evaluate the effect of pregnancy on the pelvic floor (Boreham, 2005).

NORMAL VAGINAL FLORA

Vaginal flora of a normal asymptomatic reproductive-aged woman includes multiple aerobic or facultative species as well as obligate anaerobic species (Table 3-1). Of these, anaerobes are predominant and outnumber aerobic species approximately 10 to 1 (Bartlett, 1977).

One study of 55 asymptomatic reproductive-aged women found a mean of 4.2 and 2.1 bacterial species recovered from the endocervix and the endometrial cavity, respectively (Hemsell, 1989). Of the species recovered, 17 percent were recovered from the endometrium only, 50 percent were recovered from the endocervix only, and the remainder was recovered from both sites. This implies that there is access to the upper reproductive tract by certain bacterial species normally found in vaginal flora.

The function of and reason for bacterial colonization of the vagina remains unknown. Bacteria do exist in a symbiotic relationship with the host and are alterable, depending on the microenvironment. These organisms localize where their survival needs are met, and have exemption from the infection-preventing destructive capacity of the host.

Within this vaginal ecosystem, some microorganisms produce substances such as lactic acid and hydrogen peroxide that inhibit nonindigenous organisms (Marrazzo, 2006). In addition, several other antibacterial compounds, termed *bacteriocins,* provide a similar role and include peptides such as acidocin and lactacin. Moreover, some species have the ability to produce proteinaceous adhesions and attach to vaginal epithelial cells.

For protection from many of these toxic substances, the vagina secretes leukocyte protease inhibitor. This protein protects local tissues against toxic inflammatory products and infection.

Vaginal pH

Typically, the vaginal pH ranges between 4 and 4.5. Although not completely understood, it is believed to result from *Lactobacillus* species' production of lactic acid, fatty acids, and other organic acids. In addition, amino acid fermentation by anaerobic bacteria results in organic acid production as does bacterial protein catabolism. Glycogen present in healthy vaginal mucosa is believed to

provide nutrients for many species in the vaginal ecosystem. Accordingly, as glycogen content within vaginal epithelial cells diminishes after menopause, this decreased substrate for acid production leads to a rise in vaginal pH (Chap. 21, Lower Reproductive Tract Changes). Specifically, Caillouette and associates (1997) showed that a vaginal pH of 6.0 to 7.5 was strongly suggestive of menopause in the absence of symptoms. Moreover, serum follicle-stimulating hormone (FSH) levels and vaginal pH were positively correlated, whereas an inverse relationship was noted between those two and serum estradiol levels.

Altered Flora

Changing any element of this ecology may alter the prevalence of various species. For example, postmenopausal women not receiving estrogen replacement and young girls have a lower prevalence of *Lactobacillus* species compared with reproductive-aged women. Devillard and colleagues (2004) reported that hormone replacement therapy restored vaginal lactobacilli populations, which protected against reproductive tract pathogens.

The menstrual cycle may also alter normal flora. Transient changes are observed, predominantly during the first part of the menstrual cycle, and are presumed to be associated with hormonal changes (Keane, 1997).

Several other events predictably alter lower reproductive tract flora and may lead to patient infection. Treatment with a broad-spectrum antibiotic or menstruation may result in symptoms attributed to inflammation from *Candida albicans* or other *Candida* species. Menstrual fluid also may serve as a source of nutrients for several bacterial species, resulting in their overgrowth. What role this plays in the development of upper reproductive tract infection following menstruation is unclear, but an association may be present.

Hysterectomy with removal of the cervix changes lower reproductive tract flora, with or without prophylactic antimicrobial administration. Usually, more anaerobic species are recovered from the vagina postoperatively, with a particular increase in the prevalence of *Bacteroides fragilis.* Increased prevalence is also observed for *Escherichia coli* and *Enterococcus* species. These three species are frequently observed in cultures obtained from women who develop pelvic infections following hysterectomy, but similar increases are also seen in vaginal cultures obtained after hysterectomy in asymptomatic patients (Hemsell, 1988; Ohm, 1975).

Bacterial Vaginosis (BV)

This common and complex clinical syndrome reflects abnormal vaginal flora, and is poorly understood. It has been variously named, and former terms include *Haemophilus* vaginitis, *Corynebacterium* vaginitis, *Gardnerella* or anaerobic vaginitis, and nonspecific vaginitis.

For unknown reasons, the vaginal flora's symbiotic relationship shifts to one in which there is overgrowth of anaerobic species including *Gardnerella vaginalis, Ureaplasma urealyticum, Mobiluncus* species, *Mycoplasma hominis,* and *Prevotella* species. Bacterial vaginosis (BV) is also associated with a significant reduction or absence of the normal hydrogen peroxide-producing *Lactobacillus* species. Whether an altered ecosystem leads to lactobacilli disappearance or whether its disappearance results in the changes observed with BV is unknown.

RISK FACTORS

This condition is not considered by the Centers for Disease Control and Prevention (CDC) consensus group to be a sexually transmitted disease (STD), and it is seen in women without previous sexual experience. Many risk factors, however, are associated with sexual activity, and an increased risk of acquiring STDs has been reported in affected women (Table 3-2). Moreover, a possible role of sexual transmission in the pathogenesis of recurrent BV has been proposed by Bradshaw and colleagues (2006). Successful prevention of BV is limited, but elimination or diminished use of vaginal douches may be beneficial.

DIAGNOSIS

Bacterial vaginosis is reported by some to be the most frequent cause of vaginal symptoms resulting in health care visits. Of symptoms, a nonirritating, malodorous vaginal discharge is characteristic, but may not always be present. The vagina is usually not erythematous, and cervical examination reveals no abnormalities.

Clinical diagnostic criteria were first proposed by Amsel and associates (1983) and include: (1) microscopic evaluation of a saline "wet prep" of vaginal secretions, (2) determination of the vaginal pH, and (3) release of volatile amines produced by anaerobic metabolism. Clue cells are the most reliable indicators of BV and were originally described by Gardner and Dukes (1955) (Fig. 3-1). These vaginal epithelial cells contain many attached bacteria, which create a poorly defined stippled cellular border. The positive predictive value of this test for the presence of BV is 95 percent.

FIGURE 3-1

Photograph of saline wet preparation reveals clue cells. Squamous cells are covered with bacteria to the extent that cell borders are blurred and nuclei are not visible. A saline preparation, also termed a *wet prep,* is made by mixing a sample of vaginal discharge obtained with a cotton swab and a few drops of saline on a microscope slide. *(From Kuhn, 2004, with permission.)*

Adding 10 percent potassium hydroxide (KOH) to a fresh sample of vaginal secretions releases volatile amines that have a fishy odor. This is often colloquially referred to as a *whiff test.* The odor is frequently evident even without KOH. Similarly, alkalinity of seminal fluid and blood are responsible for odor complaints after intercourse and with menses. The finding of both clue cells and a positive whiff test is pathognomonic, even in asymptomatic patients.

Characteristically with BV, the vaginal pH is >4.5 and results from diminished acid production by bacteria. Similarly, *Trichomonas vaginalis* infection is also associated with anaerobic overgrowth and resultant elaborated amines. Thus, women diagnosed with BV should have no microscopic evidence of trichomoniasis.

Several gynecologic adverse health outcomes have been observed in women with BV, including vaginitis, endometritis, postabortal endometritis, pelvic inflammatory disease unassociated with *Neisseria gonorrhoeae* or *Chlamydia trachomatis,* and acute pelvic infections following pelvic surgery, especially hysterectomy.

TREATMENT

Three regimens have been proposed by the 2006 Centers for Disease Control and Prevention BV working group and are for nonpregnant women (Table 3-3). Cure rates with these regimens range from 80 to 90 percent at 1 week, but within 3 months, 30 percent of women have experienced a recurrence of altered flora. At least half have another episode of symptoms associated with this flora change, many of which are correlated with heterosexual contacts (Amsel, 1983; Gardner, 1955; Wilson, 2004). However,

treatment of male sexual partners does not benefit women with this recurring condition and is not recommended. Moreover, other forms of therapy such as introduction of lactobacilli, acidifying gel, and use of probiotics have shown inconsistent effectiveness.

Agent	Dosage
Metronidazole	500 mg orally twice daily for 7 days
Metronidazole gel 0.75%	5 g (1 full applicator) intravaginally once daily for 5 days
Clindamycin cream 2%	5 g (1 full applicator) intravaginally at bedtime for 5 days

ANTIBIOTICS

Antibiotics are commonly used in gynecology to restore altered flora or treat various infections. The ideal antibiotic is one that exhibits almost complete bioavailability from either oral or parenteral administration, acts promptly to eradicate a diverse variety of aerobic and anaerobic bacteria, fails to induce bacterial resistance, and is nontoxic, nonsensitizing, inexpensive, and easily produced. It does not exist. Despite this, there are many effective antibiotics available for the treatment of gynecologic infection.

Penicillins

STRUCTURE

The heart of all penicillins is a thiazolidine ring with an attached β-lactam ring and a side chain (Fig. 3-2). The β-lactam nucleus provides antibacterial activity, which is primarily against gram-positive aerobic bacteria. Because of the numerous substitutions at R_1 , a variety of antibiotics with altered antibacterial spectra and pharmacologic properties have been synthesized (Table 3-4). In addition, clavulanic acid and sulbactam β-lactamase inhibitors have been combined with one of several existing penicillins. This enhances the spectrum of activity against a broader variety of aerobic and anaerobic bacteria, whose primary defense mechanism is production of an enzyme (β-lactamase) that opens the β-lactam ring, inactivating the antibiotic.

ADVERSE REACTIONS

Table 3-5 lists adverse reactions to penicillins (Mayo Clinic, 1991). Up to 10 percent of the general population may manifest an allergic reaction to penicillins. The lowest risk is associated with oral preparations, whereas the highest follows those combined with procaine and given intramuscularly. True anaphylactic reactions are rare, and mortality ranges between 1 in every 50,000 to 60,000 treatment regimens. If penicillin allergy is noted, yet treatment is still required, desensitization can be performed as described by Wendel and co-workers (1985) and outlined at the CDC website: http://www.cdc.gov/std/treatment/2006/penicillin-allergy.htm .

CLINICAL APPLICATIONS

Excellent tissue penetration is achieved with these agents. Penicillin remains the primary drug for treatment of syphilis, and this family of antibiotics is also useful in treating skin infections and breast abscesses. Moreover, the ureidopenicillins and those combined with a β-lactamase enzyme inhibitor are effective against acute community-acquired or postoperative pelvic infections. The combination of amoxicillin and clavulanic acid provides the best oral broad-spectrum antibiotic coverage.

Cephalosporins

STRUCTURE

Cephalosporins also are β-lactam antimicrobials that are semisynthetically derived from a compound produced by the fungus *Cephalosporium acremonium.* Substitutions at the R_1 or R_2 sites of the cephalosporin nucleus significantly alter the spectrum of activity, potency, toxicity, and half-life of these antibiotics (Fig. 3-3). Organization of these qualities has resulted in their division into first-, second-, or third-generation cephalosporins. Although possibly a marketing tool, this classification does allow grouping based on general spectra of activity. Those commonly used by the gynecologists are presented in Table 3-6.

Table 3-6 Cephalosporin Classification

Chemical nuclear structure of the cephalosporins, produced by alterations in the molecular structure of the basic cephalosporin nucleus at the R_1 and R_2 positions.

ADVERSE REACTIONS

Rash and other hypersensitivity reactions are the most common, and may develop in up to 3 percent of patients. Cephalosporins are β-lactam antibiotics and, if used in those allergic to penicillin, may create the same or accentuated response. Theoretically, this may happen in up to 16 percent of patients (Saxon, 1987). Thus, if an individual developed anaphylaxis with penicillin therapy, cephalosporin administration is contraindicated.

CLINICAL APPLICATIONS

First-generation cephalosporins are used primarily for surgical prophylaxis and in the treatment of superficial skin cellulitis. Their activity spectrum is greatest against gram-positive aerobic cocci, with some activity against community-acquired gram-negative rods. However, there is little activity against β-lactamase producing organisms or anaerobic bacteria. Despite this inactivity against many pathogens of pelvic infection that may be acquired during surgery, there is prophylactic efficacy.

Second-generation cephalosporins have enhanced activity against gram-negative aerobic and anaerobic bacteria, with some diminution in effectiveness against aerobic gram-positive cocci. Their primary use is in surgical prophylaxis or for single-agent therapy of major community-acquired or postoperative pelvic infections.

Third-generation cephalosporins are effective in treatment of major postoperative pelvic infections, including abscess. However, they are used primarily in the treatment of postoperative respiratory tract infections. These agents have documented efficacy as prophylactic agents, but should be reserved for therapy.

Aminoglycosides

STRUCTURE AND CLINICAL APPLICATIONS

This family of compounds includes gentamicin, tobramycin, netilmicin, and amikacin. They differ in antimicrobial activity based on the various amino sugars that form the lateral chains of the central aminoglycoside nucleus. Of the aminoglycosides, gentamicin is primarily selected because of its low cost and clinical efficacy for pathogens recovered from pelvic infections. For gynecologists, it may be combined with clindamycin with or without ampicillin as a regimen for treatment of serious pelvic infections. Alternatively, gentamicin may be joined with ampicillin and metronidazole. Lastly, it can be used as single-agent therapy for pyelonephritis.

ADVERSE REACTIONS

Aminoglycosides have the potential for significant patient toxicity (Table 3-7). The inner ear is particularly susceptible to aminoglycosides because of selective accumulation within the hair cells and prolonged half-life within inner ear fluids. Those with vestibular toxicity complain of headaches, nausea, tinnitus, and loss of equilibrium. Cochlear toxicity results in high-frequency hearing loss. If either of these develops, aminoglycoside administration must be stopped promptly. Ototoxicity may be permanent, and risk correlates positively with dose and duration of therapy.

Table 3-7 Aminoglycoside Toxicity
Major
• Ototoxicity
Auditory
Vestibular
• Nephrotoxicity
• Neuromuscular blockade
Minor
• Skin rash
• Drug fever

Nephrotoxicity is reversible, and may develop in up to 25 percent of patients (Bertino, 1993). Risk factors include older age, renal insufficiency, hypotension, volume depletion, frequent dosing intervals, treatment for 3 or more days, multiple antibiotic administration, or multisystem disease. Toxicity leads to a nonoliguric decrease in creatinine clearance and resultant rise in serum creatinine levels.

Neuromuscular blockade is a rare but potentially life-threatening complication, and is dose-related. This family of antibiotics inhibits presynaptic acetylcholine release, blocks acetylcholine receptors, and prevents presynaptic calcium absorption. For this reason, aminoglycoside contraindications include myasthenia gravis or concurrent succinylcholine use. Blockade frequently follows rapid intravenous infusion. For this reason, aminoglycosides are ideally given intravenously over at least 30 minutes. Toxicity is usually detected before respiratory arrest, and at its first signs, intravenous calcium gluconate is administered to reverse this form of aminoglycoside toxicity.

DOSING

Multiple Doses

Aminoglycosides may be parenterally dosed every 8 hours in those with normal renal function. For critically ill patients, an initial dose of between 1.5 and 2 mg/kg for gentamicin, tobramycin, and netilmicin, and 7.5 and 15 mg/kg for amikacin is recommended. Subsequently, maintenance doses are calculated to deliver 3 to 5 mg/kg/d of ideal body weight for the first three aminoglycosides listed above and 15 mg/kg/d for amikacin.

If a patient has decreased renal function, there should be dose reduction or interval lengthening or both. The formula listed allows one to calculate a rough estimate of creatinine clearance so proper adjustments can be made. This formula is for male patients. The result, multiplied by 0.85, will give a value for female patients.

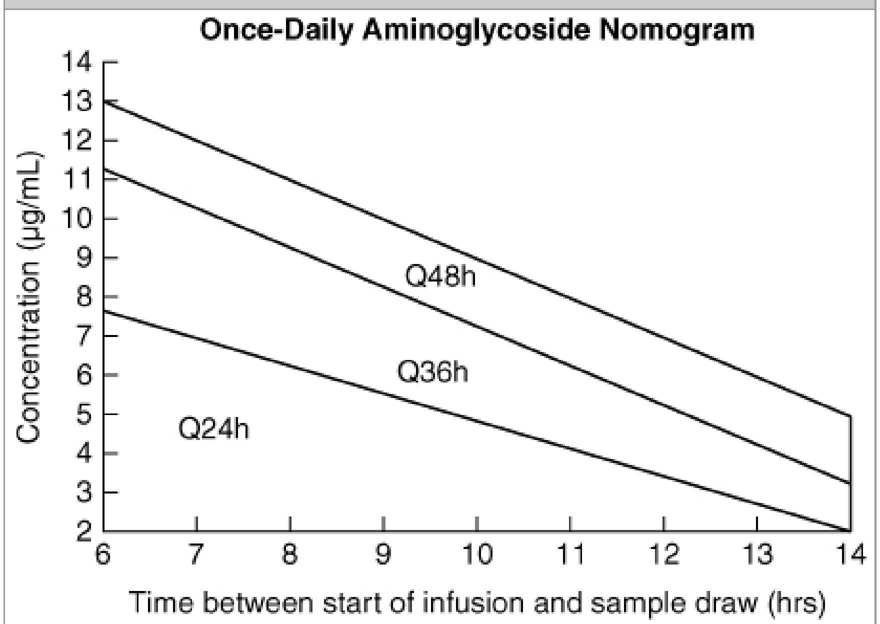
$$\text{Creatinine clearance (mL/min)} = (140 - \text{age}) \times \text{weight (kg)} \div \text{serum creatinine} \times 72$$

To monitor serum concentration, provide adequate therapeutic levels, and prevent toxicity in patients given multiple daily doses, serum aminoglycoside concentrations should be measured at two points. The first is the peak, drawn either 30 minutes after the completion of a 30-minute infusion or 1 hour after an intramuscular injection. These values for gentamicin, tobramycin, and netilmicin should be 4 to 6 μg/mL. For amikacin it should be between 20 and 30 μg/mL. The second blood sample should be drawn immediately before initiation of the next dose 7.5 or 8 hours later. Trough concentrations should be between 1 and 2 μg/mL for the first three aminoglycosides and 5 to 10 μg/mL for amikacin. These should be repeated if therapy is prolonged (3 to 4 days) or if serum creatinine levels increase. High peak and trough levels are indicators for increased risk of toxicity.

Single Daily Dosing

Increased aminoglycoside concentration enhances antibacterial activity but also toxicity. Once-daily dosing was evaluated and found to be as or less toxic than multiple daily dosing without sacrificing clinical efficacy (Bertino, 1993). Tulkens and colleagues (1988) reported that once-daily dosing of netilmicin was less toxic than administrations three times daily, without jeopardizing efficacy in the treatment of women with pelvic inflammatory disease. In 1992, Nicolau and associates presented pharmacokinetic data and a nomogram for administering aminoglycosides once daily (Fig. 3-4).

FIGURE 3-4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Once-daily aminoglycoside nomogram.

Recommendation for an initial dose, which is 7 mg/kg, is based on the patient's creatinine clearance. For those with a creatinine clearance greater than 60 mL/min, the dosing is every 24 hours. If the clearance is between 40 and 60 mL/min, the recommended dose is every 36 hours. If the clearance is less than 40 mL/min, traditional dosing is recommended.

To use the nomogram presented in Figure 3-4, one obtains a random serum concentration between 8 and 12 hours after the start

of the initial dose infusion. One then places that concentration value over the time interval to determine the dosing interval. That applies to gentamicin, tobramycin, and netilmicin. For amikacin, the initial dose is 15 mg/kg, and the resultant concentration at 8 to 12 hours should be divided by 2 and then placed on the nomogram at the dosing interval drawn.

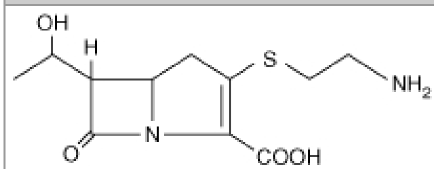
With this dosing calculation approach, standard peak and trough levels are unnecessary. A second random sample should be drawn if therapy continues for more than 4 days.

Carbapenems

STRUCTURE

The carbapenems are a third class of β-lactam antibiotics that differ from penicillins by substitution of a carbon for a sulfur atom in the five-membered ring and by the addition of a double bond therein (Fig. 3-5). The three antibiotics in this family are imipenem, meropenem, and ertapenem.

FIGURE 3-5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Basic chemical structure of carbapenems.

ADVERSE REACTIONS

Adverse reactions are comparable to those of the other β-lactam antibiotics. As is true with other β-lactams, if patients have experienced a type 1 hypersensitivity reaction to either a penicillin or a cephalosporin, then a carbapenem should not be administered.

CLINICAL APPLICATIONS

These antibiotics are designed for polymicrobial bacterial infections, primarily those with resistant aerobic gram-negative bacteria not susceptible to other β-lactam agents. They should be reserved to preserve efficacy by preventing the development of resistance.

Monobactam

The marketed monobactam, aztreonam, is a synthetic β-lactam that has a spectrum of activity similar to aminoglycosides, that is, gram-negative aerobic species. Like other β-lactam antibiotics, these compounds inhibit bacterial cell wall synthesis by binding to penicillinâ€"binding proteins or causing cell lysis. It has affinity only for the binding proteins of the gram-negative bacteria, and does not possess affinity for either gram-positive bacteria or anaerobic organisms. For the gynecologist, aztreonam provides coverage for gram-negative aerobic bacteria, which is usually provided by aminoglycosides, in patients with significantly impaired renal function or aminoglycoside allergy.

Clindamycin

Clindamycin was introduced in the mid-1960s and has been a workhorse in the treatment of serious gynecologic infections. It is a semisynthetic derivative of lincomycin, a product of the actinomycete *Streptomyces lincolnensis.*

Clindamycin is primarily active against aerobic gram-positive bacteria and anaerobic bacteria, with little activity against aerobic gram-negative bacteria. It is also active against *Chlamydia trachomatis. Neisseria gonorrhoeae* is moderately sensitive and *Gardnerella vaginalis* is very susceptible to clindamycin. It may be delivered by one of three routes: orally, vaginally (2-percent cream), or intravenously.

The principal application of clindamycin for the gynecologist has been its combination with gentamicin and administration to women with serious community-acquired or postoperative soft tissue infections or pelvic abscess. It is also used vaginally in the treatment of women with bacterial vaginosis. Because there are parenteral and oral forms of this antibiotic, conversion from the more expensive parenteral therapy to oral therapy can occur early.

Vancomycin

Vancomycin is a glycopeptide antibiotic that is active only against aerobic gram-positive bacteria. It is primarily used by the gynecologist to treat patients in whom β-lactam therapy is impossible due to a type 1 allergic reaction. Additionally, an oral dose of 120 mg every 6 hours can be given to patients who have developed antibiotic-associated *Clostridium difficile* colitis and who do not respond to oral metronidazole.

ADVERSE REACTIONS

These are presented in Table 3-8. The most remarkable of these is the "red man" syndrome, which is a dermal reaction developing usually within minutes after initiation of a rapid drug infusion. The reaction, which is a response to histamine release, is an erythematous pruritic rash involving the neck, face, and upper torso. Hypotension also may develop. Intravenous administration over 1 hour or administration of an antihistamine may be protective, if given prior to infusion. Also associated with rapid administration may be painful back and chest muscle spasms.

Table 3-8 Vancomycin Adverse Effects
Hypersensitivity reactions Drug fever (rare) Allergic rash (rare)
Infusion-related side effects Hypotension "Red man" syndrome "Pain and spasm" syndrome
Nephrotoxicity Rare Reversible Enhanced risk with concomitant aminoglycoside therapy
Neutropenia Reversible Develops after prolonged use
Ototoxicity Hearing loss: often irreversible; rare; associated with drug levels >30 μg/mL Enhanced risk with concomitant aminoglycoside therapy

Thrombophlebitis Associated with peripheral venous cannulas

The most significant of vancomycin's side effects is nephrotoxicity, which is enhanced with aminoglycoside therapy, as is ototoxicity. Both are associated with high serum concentrations of vancomycin. For that reason, serum peak and trough concentrations are recommended, and should range between 20 and 40 µg/mL and 5 and 10 µg/mL, respectively. The initial dose should be 15 mg/kg of ideal body weight.

Metronidazole

This antibiotic was approved by the Food and Drug Administration (FDA) in the early 1960s for the treatment of trichomonal infections. Metronidazole is the principal treatment for trichomonal infections. Moreover, it is one of the mainstays of combination antimicrobial therapy given to women with serious postoperative or community-acquired pelvic infections including pelvic abscess. Since it is active only against obligate anaerobes, metronidazole must be combined with agents effective against gram-positive and gram-negative aerobic bacterial species, such as ampicillin and gentamicin. This antibiotic is also useful in treatment of bacterial vaginosis, and is as effective as vancomycin in the treatment of *C difficile* â€“associated pseudomembranous colitis.

ADVERSE REACTIONS

Up to 12 percent of patients taking oral metronidazole may have nausea, and an unpleasant metallic taste has also been described. Patients should abstain from alcohol use to avoid a disulfiram-like effect and emesis. Peripheral neuropathy and convulsive seizures have been reported, are probably dose-related, and are rare.

Fluoroquinolones

This is a new and rapidly developing antibiotic class. Also known simply as *quinolones,* these drugs have become first-line agents for treating a variety of infections because of their excellent bioavailability with oral administration, tissue penetration, broad-spectrum antibacterial activity, long half-lives, and good safety profile. As with cephalosporins, fluoroquinolones are separated into generations by their development, antibacterial activity, and pharmacokinetic properties (Table 3-9).

Table 3-9 Selected Quinolone Antibiotics

First-Generation	Second-Generation	Third-Generation
Nalidixic acid	Norfloxacin	Levofloxacin
	Ciprofloxacin	Sparfloxacin
	Ofloxacin	Clinafloxacin
	Lomefloxacin	Sitafloxacin
	Enoxacin	Gatifloxacin
	Fleroxacin	Moxifloxacin
	Pefloxacin	Gemifloxacin

ADVERSE REACTIONS

Quinolones are contraindicated in children, adolescents, and pregnant and breastfeeding women because they may affect cartilage development. As a family, they are safe, and severe adverse reactions are rare. The side effect rate ranges from 4 to 8 percent, and primarily affects the gastrointestinal (GI) tract following oral administration. Central nervous system symptoms such as headache, confusion, tremors, and seizures have been described, and these develop more frequently in patients with underlying brain

disorders.

CLINICAL APPLICATIONS

These agents are widely used by gynecologists to treat urinary tract, sexually transmitted and bacterial intestinal infections, and pelvic inflammatory disease. However, they should not be overused. If a less expensive, safer, and equally effective alternative agent is available to treat a given infection, it should be used to preserve fluoroquinolone efficacy.

PATHOGENS CAUSING GENITAL ULCER INFECTIONS

Ulceration defines complete loss of the epidermal covering with invasion into the underlying dermis, whereas *erosion* describes partial loss of the epidermis without dermal penetration. These are distinguished by clinical examination. Biopsies are generally not helpful, but may be if taken from the edge of a new lesion. Importantly, biopsy is mandatory if carcinoma is suspected (see Chap. 4, Vulvar Biopsy).

Most young sexually active women in the United States who have genital ulcers will have herpes simplex infection, syphilis, or chancroid, but some will have lymphogranuloma venereum or granuloma inguinale. Essentially all are sexually transmitted and are associated with increased risk for human immunodeficiency virus (HIV) infections. For this reason, HIV and other sexually transmitted disease testing should be offered to such patients. Sexual contacts require examination and treatment, and both require re-evaluation following treatment.

Herpes Simplex Virus Infection

Genital herpes is the most prevalent genital ulcer disease and is a chronic viral infection. The virus enters sensory nerve endings and undergoes retrograde axonal transport to the dorsal root ganglion, where the virus develops lifelong latency. Spontaneous reactivation by various events results in anterograde transport of virus particles/protein to the surface. Here virus is shed, with or without lesion formation. It is postulated that immune mechanisms control latency and reactivation (Cunningham, 2006).

There are two types of herpes simplex virus, HSV-1 and HSV-2. Type 1 HSV is the most frequent cause of oral lesions. Type 2 HSV is found more typically with genital lesions, although both types can cause genital herpes. It is estimated that 26 percent of American females age 12 and older have suffered a genital HSV-2 infection, and 40 percent of adults are seropositive to HSV-1.

Most women who have been infected with HSV-2 lack this diagnosis because of mild or unrecognized infections. Infected patients can shed infectious virus while asymptomatic, and most infections are transmitted sexually by patients that are unaware of their infection. Most (65 percent) with active infection are women.

SYMPTOMS

Patient symptoms at initial presentation will depend primarily on whether or not a patient during the current episode has antibody from previous exposure. If a patient has no antibody, the attack rate in an exposed person approaches 70 percent. The mean incubation period is about 1 week. Up to 90 percent of those who are symptomatic with their initial infection will have another episode within a year.

Burning and severe pain accompany initial vesicular lesions, and urinary symptoms such as frequency and/or dysuria may be present with those of the vulva (Fig. 3-6). The virus infects viable epidermal cells, the response to which is erythema and papule formation. With cell death and cell wall lysis, blisters form. The covering then disrupts, leaving a usually painful ulcer. These lesions develop crusting and heal, but may become secondarily infected. The three stages of lesions are: (1) vesicle with or without pustule formation, which lasts about a week; (2) ulceration; and (3) crusting. Virus is predictably shed during the first two phases of an infectious outbreak. Angiomyopathy may result from vulvar lesions, and may cause urethral obstruction. Alternatively or additionally, herpetic lesions may involve the vagina, cervix, bladder, and rectum. Commonly, a woman may have other signs of viremia such as a low-grade fever, malaise, and cephalalgia.

FIGURE 3-6

Genital herpetic ulcers. *(Courtesy of Dr. William Griffith.)*

Viral load undoubtedly contributes to the numbers, size, and distribution of lesions. Normal host defense mechanisms inhibit viral growth, and healing starts within 1 to 2 days. Early treatment with an antiviral medication decreases the viral load.

For a previously uninfected patient, the vesicular, or initial stage, is longer. There is an increased period of new lesion formation and a longer time to healing. Pain persists for the first 7 to 10 days, and lesion healing requires 2 to 3 weeks.

If a patient has had prior exposure to HSV-2, the initial episode is significantly less severe, with shorter pain and tenderness duration, and time to healing approximates 2 weeks. Virus is shed usually only during the first week.

Recurrence following HSV-2 infection is common, and almost two thirds of patients have a prodrome prior to lesion onset. Heralding paresthesias are frequently described as pruritus or tingling in the area prior to lesion formation. However, prodromal symptoms may develop without actual lesion formation. Clinical manifestations for women with recurrences are more limited, with only about a week of symptoms.

DIAGNOSIS

The gold standard for the diagnosis of a herpetic lesion(s) is tissue culture. Specificity is high, but sensitivity is low, and declines as lesions heal. In recurrent disease, less than 50 percent of cultures are positive. Polymerase chain reaction (PCR) testing is 1.5 to 4 times more sensitive than culture and will probably replace it. Importantly, a negative culture result does not mean that there is no herpetic infection. Serologic type-specific glycoprotein Gâ€"based assays are available to detect HSV-1 and HSV-2 antibodies with a specificity ≥96 percent. The sensitivity of HSV-2 antibody testing ranges from 80 to 98 percent. Although these tests may be used to confirm herpes simplex infection, treatment and additional STD screening may be initiated in clinically obvious cases following

physical examination alone.

TREATMENT

Care Overview

Clinical management is with currently available antiviral therapy. Analgesia with nonsteroidal anti-inflammatory drugs or a mild narcotic such as acetaminophen with codeine may be prescribed. In addition, topical anesthetics such as lidocaine ointment may provide relief. Local care to prevent secondary bacterial infection is important.

Patient education is mandatory and specific topics should include the natural disease history, its sexual transmission, methods to reduce transmission, and obstetric consequences. Acquisition of this infection may have significant psychological impact, and several websites provide patient information and support. The CDC website can be accessed at http://www.cdc.gov/std/Herpes/STDFact-Herpes.htm .

Women with genital herpes should refrain from sexual activity with uninfected partners when prodrome symptoms or lesions are present. Latex condom use potentially reduce the risk for herpetic transmission.

ANTIVIRAL THERAPY

Currently available antiviral therapy includes acyclovir (Zovirax, generic); famciclovir (Famvir, Novartis, East Hanover, NJ); and valacyclovir (Valtrex, GlaxoSmithKline, Philadelphia, PA). The CDC-recommended oral medications regimens are listed in Table 3-10. Although these agents may hasten healing and decrease symptoms, therapy does not eradicate latent virus nor affect future history of recurrent infections.

Table 3-10 Recommended Oral Medication Regimens for Treatment of Genital Herpes Simplex Infection
First Clinical Episode of Genital Herpes Acyclovir 400 mg three times daily for 7 to 10 days ***or*** Acyclovir 200 mg five times daily for 7 to 10 days ***or*** Famciclovir 250 mg three times daily for 7 to 10 days ***or*** Valacyclovir 1 g twice daily for 7 to 10 days
Episodic Therapy for Recurrent Disease Acyclovir 400 mg three times daily for 5 days ***or*** Acyclovir 800 mg twice daily for 5 days ***or*** Acyclovir 800 mg three times daily for 2 days ***or*** Famciclovir 125 mg twice daily for 5 days ***or*** Famciclovir 1g twice daily for 1 day

or

Valacyclovir 500 mg twice daily for 3 days

or

Valacyclovir 1 g once daily for 5 days.

Oral Suppressive Therapy Options

Acyclovir 400 mg twice daily

or

Famciclovir 250 mg twice daily

or

Valacyclovir 0.5 to 1 g once daily

Adapted from Centers for Disease Control and Prevention, 2006, with permission.

For women with established HSV-2 infection, therapy may not be necessary if their symptoms are minimal and tolerated by the patient. Episodic therapy for recurrent disease should be initiated at least within 1 day of lesion outbreak or during the prodrome, if it exists. Ideally, patients should have medication available to begin therapy with prodromal symptoms.

If episodes recur at intervals of 2 to 3 months, a woman may elect daily suppressive therapy, which reduces recurrences by 70 to 80 percent. Safety and efficacy data with acyclovir in such patients for up to 6 years of surveillance are available. Suppressive therapy may eliminate recurrences and decreases sexual transmission of virus by approximately 50 percent (Corey, 2004). Once-daily dosing may result in enhanced compliance and decreased cost.

Syphilis

PATHOPHYSIOLOGY

Syphilis is a sexually transmitted infection caused by the spirochete *Treponema pallidum,* which is a slender spiral-shaped organism with tapered ends (Fig. 3-7). Women at highest risk are those from lower socioeconomic groups, adolescents, those with early onset of sexual activity, and those with a large number of lifetime sexual partners. The attack rate for this infection approximates 30 percent.

FIGURE 3-7

Microscopic views of *Treponema pallidum.* With dark-field microscopy, spirochetes appear as motile, bright corkscrews against a black background *(From Thompson, 1990, with permission).*

Primary Syphilis

The natural history of syphilis in *untreated* patients can be divided into four stages. The hallmark lesion of this infection is termed a *chancre,* in which spirochetes are abundant. Classically, it is an isolated nontender ulcer with raised rounded borders and an uninfected but integrated base. However, it may become secondarily infected and painful. Chancres are commonly found on the cervix, vagina, or vulva, but may also form in the mouth or around the anus (Fig. 3-8). This lesion may develop 10 days to 12 weeks after exposure, with a mean incubation period of 3 weeks. The incubation period is directly related to inoculum size. Without treatment, these lesions spontaneously heal in up to 6 weeks.

Vulvar syphilitic chancre. *(From Wilkinson, 1995, with permission.)*

Secondary Syphilis

This phase is associated with bacteremia and develops 6 weeks to 6 months after a chancre appears. Its hallmark is a maculopapular rash that may involve the entire body and includes the palms, soles, and mucous membranes (Fig. 3-9). As is true for the chancre, this rash actively sheds spirochetes. In warm, moist body areas, this rash may produce broad, pink or gray-white, highly infectious plaques called *condylomata lata* (Fig. 3-10). Because syphilis is a systemic infection, other manifestations may include fever and malaise. Moreover, organ systems such as the kidney, liver, joints, and central nervous system (CNS) (meningitis) may be involved.

Latent Syphilis

During the first year following secondary syphilis without treatment, termed *early latent syphilis,* secondary signs and symptoms may recur. However, lesions associated with these outbreaks are not usually contagious. *Late latent syphilis* is defined as a period greater than 1 year after the initial infection.

Tertiary Syphilis

This phase of untreated syphilis may appear up to 20 years after latency. During this phase, cardiovascular, CNS, and musculoskeletal involvement become apparent. However, cardiovascular and neurosyphilis are half as common in females as in males.

DIAGNOSIS

Early syphilis is diagnosed primarily by dark-field examination or direct fluorescent antibody testing of lesion exudate. In the absence of this positive diagnosis, presumptive diagnosis may be reached with serologic tests that are nontreponemal: (1) Venereal Disease Research Laboratory (VDRL) or (2) rapid plasma reagin (RPR) tests (Table 3-11). Alternatively, treponemal-specific tests may be selected: (1) fluorescent treponemal antibody-absorption (FTA-ABS) or (2) *Treponema pallidum* particle agglutination (TP-PA) tests. Clinicians should be familiar with the uses of syphilis serologic tests. For population screening, RPR or VDRL testing is appropriate. For quantitative measurement of antibody titers to assess response to treatment, RPR or VDRL tests are typically used. But for diagnosis confirmation in a woman with a positive nontreponemal antibody test result or with a suspected clinical diagnosis, then FTA-ABS or TP-PA testing should be selected.

Table 3-11 Sensitivity of Serodiagnostic Tests in Untreated Syphilis

	Mean Percentage Positive (Range) at Indicated Stage of Disease[b]			
Test[a]	**Primary**	**Secondary**	**Latent**	**Tertiary**
VDRL, RPR	78 (74â€“87)	100	95 (88â€“100)	71 (37â€“94)
FTA-ABS	84 (70â€“100)	100	100	96
TP-PA[c]	89	100	100	NA

FTA-ABS = fluorescent treponemal antibody-absorption; NA = not available; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory; TP-PA = *Treponema pallidum* particle agglutination.

[a] The specificity for each of these tests is 94 to 99 percent.

[b] In CDC studies.

[c] Limited numbers of sera have been evaluated by TP-PA.

From Lukehart, 2007, with permission.

Following treatment, sequential nontreponemal tests should be performed. A fourfold titer decrease (two dilutions) is required to define a clinically significant decline. During surveillance, the same type test should be used. These tests usually become nonreactive after treatment and with time. However, some women may have a persistent low rating, and these patients are described as *serofast* . Women with a reactive treponemal-specific test will more than likely have a positive test for the remainder of their lives, but up to 25 percent may revert to a negative result after several years.

TREATMENT

Since 1943, penicillin has been the first-line therapeutic agent for this infection, and benzathine penicillin is primarily chosen. Specific recommendations for therapy by the CDC (2006) are listed in Table 3-12. With treatment, an acute, self-limited febrile response, termed a *Jarisch-Herxheimer reaction,* may develop within the first 24 hours after treatment of early disease and is associated with headache and myalgia.

Table 3-12 Recommended Treatment of Syphilis

Primary, secondary, early latent (<1 year) syphilis
Recommended regimen:
Benzathine penicillin G, 2.4 million units IM once
Alternative oral regimens (penicillin-allergic, nonpregnant women):
Doxycycline 100 mg orally twice daily for 2 weeks
or
Tetracycline 500 mg orally four times daily for 2 weeks
Late latent, tertiary, and cardiovascular syphilis
Recommended regimen:
Benzathine penicillin G, 2.4 million units IM weekly times 3 doses

Alternative oral regimen (penicillin-allergic, nonpregnant women):
Doxycycline 100 mg orally twice daily for 4 weeks

From Centers for Disease Control and Prevention, 2006, with permission.

As with other STDs, all patients treated for syphilis should be tested for other STDs. Patients with evidence of neurologic or cardiac involvement should be treated by an infectious disease specialist. After initial treatment, women should be seen at 6-month intervals for clinical evaluation as well as serologic retesting. A four fold dilution decrease is anticipated. If this does not occur, a patient has either failed treatment or was re-infected and should be re-evaluated and retreated. Retreatment recommendations are benzathine penicillin G, 2.4 million units IM weekly for 3 weeks.

Alternative treatment to intramuscular penicillin involves regimens with oral tetracyclines. Thus, if patients with penicillin allergy cannot be followed or if their compliance is questioned, then skin testing, desensitization, and treatment with IM benzathine penicillin is recommended (Wendel Jr., 1985).

Chancroid

Chancroid is one of the classical sexually transmitted diseases, but is an uncommon infection in the United States. It appears as local outbreaks predominantly in black and Hispanic males.

It is caused by a nonmotile, nonspore-forming, facultative, gram-negative bacillus, *Haemophilus ducreyi.* Incubation usually spans 3 to 10 days, and host access probably requires a break in the skin or mucous membrane. Chancroid does not cause a systemic reaction, and no prodromal syndrome precedes the appearance of infection.

SYMPTOMS

This disease presents initially as an erythematous papule that becomes pustular and within 48 hours, ulcerates. Edges of these painful ulcers are usually irregular with erythematous nonindurated margins. The ulcer bases are usually red and granular, and in contrast to a syphilitic chancre, are typically soft. Lesions are frequently covered with purulent material, and if secondarily infected, a foul odor will result.

The most common locations in women include the fourchette, vestibule, clitoris, and labia. Ulcers on the cervix or vagina may be nontender. Concurrently, approximately half of patients will develop unilateral or bilateral tender inguinal lymphadenopathy. If large and fluctuant, they are termed *buboes* . These may occasionally suppurate and form fistulas, the drainage from which will result in other ulcer formation.

DIAGNOSIS

The diseases most commonly imitating this presentation are syphilis and genital herpes (Fig. 3-11). These may co-exist, but uncommonly.

FIGURE 3-11

Drawing depicts the differences in clinical appearance among chancroid, syphilis, and genital herpes. These are the three most common infectious diseases manifested by genital ulcers. *(From Schmid, 1990, with permission.)*

Definitive diagnosis requires growth of *H ducreyi* on special media, but sensitivity for culture is less than 80 percent. A presumptive diagnosis can be made with identification of gram-negative, nonmotile rods on a Gram stain of lesion contents. Before obtaining either specimen, superficial pus or crusting should be removed with sterile, saline-soaked gauze.

TREATMENT

The CDC's (2006) recommended regimens for nonpregnant women are found in Table 3-13. Successful treatment will result in symptomatic improvement within 3 days, and objective evidence of improvement within 1 week. Lymphadenopathy resolves more slowly, and if fluctuant, incision and drainage may be warranted. Those with co-existing HIV infection may require longer therapy courses, and treatment failures are more common. Accordingly, some recommend longer regimens for initial management of known HIV-infected patients.

Granuloma Inguinale

Granuloma inguinale genital ulcerative disease is also known as donovanosis, and is caused by the intracellular gram-negative bacterium *Calymmatobacterium (Klebsiella) granulomatis.* This bacterium is encapsulated and has a characteristic appearance in tissue biopsy or cytology specimens (Fig. 3-12). Apparently this disease is only mildly contagious, requires repeated exposures, and has a long incubation period of weeks to months.

Photomicrograph of a mononuclear cell containing Donovan bodies. Wright-Giemsa staining creates a "closed safety pin" appearance. *(From Kellogg, 1990, with permission.)*

SYMPTOMS

Granuloma inguinale presents as painless inflammatory nodules that progress to highly vascular, beefy red ulcers that bleed easily on contact. If secondarily infected they may become painful. These ulcers heal by fibrosis, which can result in scarring resembling keloids. Lymph nodes are usually uninvolved, but may become enlarged, and new lesions may appear along these lymphatic drainage channels. Distant lesions have also been reported.

DIAGNOSIS

Diagnosis is confirmed by identification of Donovan bodies during microscopic evaluation of a specimen following Wright-Giemsa staining. Currently, there are no FDA-approved PCR tests for *C granulomatis* DNA.

TREATMENT

Treatment does stop lesion progression and may be lengthy without formation of granulation tissue in ulcer bases and re-epithelialization (Table 3-14). Relapses have been reported up to 18 months after "effective" treatment. A few prospective treatment trials have been published, but these are limited. If successful, improvement will be evident within the first few days of treatment.

Lymphogranuloma Venereum (LGV)

This ulcerative genital disease is caused by *Chlamydia trachomatis,* serotypes L1, L2, and L3. Lymphogranuloma venereum (LGV) is uncommon in the United States. As is true with other sexually transmitted diseases, this infection is found in lower socio-economic groups among sexually promiscuous persons.

The chlamydial life cycle is comprised of three stages. Initially, infective particles (elementary bodies) penetrate a host cell. Here they develop into metabolically active reticulate bodies. Binary fission within the cell allows reticulate bodies to transform themselves into multiple elementary bodies, which are released by exocytosis.

SYMPTOMS

This infection is commonly divided into three stages as follows: stage 1â€”small vesicle or papule; stage 2â€”inguinal or femoral lymphadenopathy; and stage 3â€”anogenitorectal syndrome. Incubation for this infection ranges from 3 days to 2 weeks. Initial papules heal quickly and without scarring. They appear primarily on the fourchette and posterior vaginal wall up to and including the cervix. Repeated inoculation may result in lesions at multiple sites.

During the second stage, sometimes referred to as the *inguinal syndrome,* progressive enlargement of inguinal and femoral lymph nodes is observed. Enlarged painful nodes can mat together and create a characteristic "groove sign", which appears in up to one fifth of infected women (Fig. 3-13). In addition, enlarging nodes may rupture through the skin, and chronically draining sinuses may result. Fever may be noted prior to rupture. Commonly, women with LGV develop systemic infection with chlamydia and manifest malaise and fever. Additionally, pneumonitis, arthritis, and hepatitis have been reported with this infection.

Photograph of the "groove sign" seen with lymphogranuloma venereum. Enlarged lymph nodes matted together on either side of the inguinal ligament create this characteristic groove. *(From Barnes, 1990, with permission.)*

In the third stage of LGV, a patient develops rectal pruritus and a mucoid discharge from rectal ulcers. If these become infected, the discharge becomes purulent. This presentation is a result of lymphatic obstruction that follows lymphangitis and that may result in elephantiasis of external genitalia initially and fibrosis of the rectum. Rectal bleeding is common, and a woman may complain of crampy, abdominal pain with abdominal distention, rectal pain, and fever. Peritonitis may follow bowel perforation. Stenosis of the urethra and the vagina has also been reported.

DIAGNOSIS

Lymphogranuloma venereum may be diagnosed following clinical evaluation with exclusion of other etiologies and positive chlamydial testing. A serologic titer that is greater than 1:64 can support the diagnosis. Additionally, lymph node specimens obtained by swab or aspiration may be cultured for *C trachomatis* or tested by immunofluorescence or PCR.

TREATMENT

The 2006 CDC-recommended regimen is doxycycline, 100 mg orally twice daily for 21 days. Alternatively, one may use erythromycin base, 500 mg orally four times daily, for the same duration. It is recommended that sexual contacts exposed to a patient within the prior 60 days should be tested for urethral or cervical infection, and treated with either standard antichlamydial regimen.

PATHOGENS CAUSING INFECTIOUS VAGINITIS

The term *vaginitis* is the diagnosis given to women who present complaining of abnormal vaginal discharge with vulvar burning, irritation, or itching. It is one of the most frequent reasons for patient visits to the gynecologist (American College of Obstetricians and Gynecologists, 2006). The leading causes of symptomatic vaginal discharge are bacterial vaginosis, candidiasis, and trichomoniasis.

Between 7 and 70 percent of women who have vaginal discharge complaints will have no definitive diagnosis (Anderson, 2004). For those in whom identifiable infection is absent, an inflammatory diagnosis and treatment for infection should not be given. In such instances, a woman may seek reassurance, having concern about a recent sexual exposure, and sexually transmitted disease testing may alleviate this. Importantly, during evaluation, a clinician should obtain a complete history regarding prior vaginal infections and their treatment; duration of symptoms; whether or not the patient has used over-the-counter (OTC) preparations, and if so which type and when; and a complete menstrual and sexual history. Moreover, a thorough physical examination of the vulva, vagina, and cervix should be performed. Several etiologies may be identified in the office by microscopic examination of a vaginal specimen (wet prep), and vaginal pH analysis may add supportive information (Table 3-15). Unfortunately, inexpensive laboratory testing is not as accurate as a clinician would hope (Bornstein, 2001; Landers, 2004).

Table 3-15 Summary of Characteristics of Common Vaginal Infections

Category	**Physiologic (normal)**	**Bacterial Vaginosis**	**Candidiasis**	**Trichomoniasis**	**Bacterial (streptococcal, staphylococcal, *E coli*)**
Chief complaint	None	Bad odor, increased after intercourse	Itching, burning, discharge	Frothy discharge, bad odor, dysuria, pruritis, spotting	Thin, watery discharge, pruritis
Discharge	White, clear	Thin, gray or white, adherent, often increased	White "cottage cheese like" discharge	Green-yellow, frothy, adherent, increased	Purulent
KOH "whiff test"	Absent	Present (fishy)	Absent	May be present	Absent
Vaginal pH	3.8â€“4.2	>4.5	<4.5	>4.5	>4.5
Microscopic findings	N/A	"Clue cells", slight increase in WBCs, clumps of bacteria (saline wet mount)	Hyphae and buds in 10-percent KOH solution (wet mount)	*Trichomonads* (protozoa with 3-5 flagella) may be seen moving on saline wet mount	Many WBCs

E coli = *Escherichia coli;* KOH = potassium hydroxide; N/A = not applicable; WBC = white blood cell.

Fungal Infection

This infection is most commonly caused by *Candida albicans,* which can be found in the vagina of asymptomatic patients, and is a commensal of the mouth, rectum, and vagina. Candidiasis is seen more commonly in warmer climates and in obese patients. Additionally, immunosuppression, diabetes mellitus, pregnancy, and recent broad-spectrum antibiotic use predispose women to clinical infection. It can be sexually transmitted, and several studies have reported an association between candidiasis and orogenital sex (Bradshaw, 2005; Geiger, 1996).

DIAGNOSIS

Symptoms of candidiasis include pruritus, pain, and swelling. In addition, vulvar erythema and edema with excoriations are common findings (Fig. 3-14). The typical vaginal discharge is described as a cottage cheese-like discharge. Vaginal pH is normal

(less than 4.5) and microscopic examination of vaginal discharge with saline and 10-percent KOH allows yeast identification (Fig. 3-15). *Candida albicans* is dimorphic with both yeast buds and hyphal forms. It may be present in the vagina as a filamentous fungus (pseudohyphae) or as germinated yeast with mycelia. Vaginal candidal culture is not routinely recommended. However, it may be warranted for those who fail empiric treatment and for women with evidence of infection, yet absence of microscopic yeast.

TREATMENT

The CDC vulvovaginal candidiasis classification (2006) is presented in Table 3-16. Various treatment formulations that are effective in treating both uncomplicated and complicated infection are presented in Table 3-17. For uncomplicated infection, azoles are extremely effective, but women should be encouraged to return if therapy is unsuccessful.

Women who have four or more candidal infections during a year are classified as having complicated disease, and cultures should

be obtained to confirm the diagnosis. Non-*albicans* candidal species are not as responsive to topical azole therapy. Therefore, prolonged local intravaginal therapy regimens and addition of oral fluconazole, one to three times a week, may be required to achieve clinical cure. Primary treatment for prevention of recurrent infection is oral fluconazole, 100 to 200 mg weekly for 6 months. For non-*albicans* recurrent infection, a 600-mg boric acid gelatin capsule intravaginally daily for 2 weeks has been successful.

Oral azole therapy has been associated with elevation in liver enzymes. Thus, prolonged oral therapy may not be feasible for that reason or because of interactions with other patient medications such as calcium channel blockers, warfarin, protease inhibitors, trimetrexate, terfenadine, cyclosporine A, phenytoin, and rifampin. In these cases, local intravaginal therapy once or twice weekly may give a similar clinical response.

Trichomoniasis

EPIDEMIOLOGY

This infection is the most prevalent nonviral STD in the United States (Van der Pol, 2005, 2007). Unlike other STDs, its incidence appears to increase with age in some studies. Trichomoniasis is more commonly diagnosed in women because most men are asymptomatic. However, up to 70 percent of male partners of women with vaginal trichomoniasis will have trichomonads in their urinary tract.

This parasite is usually a marker of high-risk sexual behavior, and co-infection with other sexually transmitted pathogens is common, especially *Neisseria gonorrhoeae. Trichomonas vaginalis* has predilection for squamous epithelium, and lesions may increase accessibility to other sexually transmitted species. Vertical transmission during birth is possible and may persist for a year.

DIAGNOSIS

Incubation with *T vaginalis* requires 3 days to 4 weeks, and the vagina, urethra, endocervix, and bladder can be infected. No symptoms may be noted in up to one-half of women with trichomoniasis, and such colonization may persist for months or years in some women. However, in those with complaints, vaginal discharge is typically described as foul, thin, and yellow or green. Additionally, dysuria, dyspareunia, vulvar pruritus, and pain may be noted. At times, symptomatology and physical findings are identical to those of acute pelvic inflammatory disease.

With trichomoniasis, the vulva may be erythematous, edematous, and excoriated. The vagina contains the above-described discharge, and subepithelial hemorrhages or "strawberry spots" may be seen on the vagina and cervix. Trichomoniasis is typically diagnosed by microscopic identification of parasites in a saline preparation of the discharge. Trichomonads are anteriorly flagellated, and therefore mobile, anaerobic protozoa. They are oval and slightly larger than a white blood cell (WBC) (Fig. 3-16). Trichomonads become less motile with cooling, and slides should be read within 20 minutes. Inspection of a saline preparation is highly specific, yet sensitivity is not as high as hoped (60 to 70 percent). In addition to microscopy, vaginal pH is often elevated.

FIGURE 3-16

Trichomonads. **A.** Photomicrograph of a vaginal smear saline preparation containing trichomonads (**arrows**). *(From Hansfield, 1992, with permission.)* **B.** Drawing depicts anatomic features of trichomonads. Flagella allow this parasite to be motile. *(From Brooks, 2004, with permission.)*

The most sensitive diagnostic technique is culture, which is impractical because special media (Diamond media) is required and few laboratories are equipped. Moreover, nucleic acid amplification tests (NAAT) for trichomonal DNA are sensitive and specific, but not widely available. Alternatively, the OSOM Trichomonas Rapid Test (Genzyme, Cambridge, MA) is an immunochromatographic assay, which has 88 percent sensitivity and 99 percent specificity. It is available for office use, and results are available in 10 minutes (Huppert, 2005). Trichomonads may also be noted on Pap smear screening and sensitivity approximates 60 percent.

Women with trichomonal infection should be tested for other sexually transmitted infections. Additionally, sexual contact(s) should be evaluated or referred for evaluation.

TREATMENT

Oral regimens recommended by the CDC (2006) are found in Table 3-18. Although each is effective, some report that a 7-day treatment regimen with metronidazole may be more effective in compliant patients. However, compliance may be poor because of longer treatment length and metronidazole side effects. Adverse effects may include a metallic taste and a disulfiram-like reaction if combined with alcohol. Accordingly, patients should abstain from alcohol during use and for 24 hours following metronidazole therapy and for 72 hours after tinidazole (Tindimax, Mission Pharmacal, San Antonio, TX).

or
Tinidazole single 2-g dose orally

Patients who become asymptomatic or who are asymptomatic do not require routine re-evaluation. However, recurrence occurs in approximately 30 percent of patients. Condom use may be protective.

There are infrequent patients who have strains that are highly resistant to metronidazole, but these organisms are usually sensitive to tinidazole. Culture and sensitivity should be performed on specimens from patients with frequently recurring infections or from those who do not respond to the initial therapy and who are medication compliant. Oral tinidazole at doses of 500 mg orally three times daily for 7 days or four times daily for 14 days have been effective in curing patients with resistant organisms (Sobel, 2001).

PATHOGENS CAUSING SUPPURATIVE CERVICITIS

Neisseria gonorrhoeae

Gonococcal infections among women are frequently asymptomatic. For that reason, it is essential that women at risk be screened periodically (see Table 1-2). Risk factors for gonococcal carriage and potential upper reproductive tract infection are: age less than 25 years, the presence of other sexually transmitted infections, a history of previous gonococcal infection, new or multiple sexual partners, lack of barrier protection, drug use, and commercial sex work. Screening for women at low risk is not recommended (U.S. Preventive Services Task Force, 2005).

SYMPTOMS

Symptomatic gonorrhea may present as vaginitis or cervicitis. Those with cervicitis commonly describe a profuse odorless, nonirritating, and white-to-yellow vaginal discharge. Gonococcus can also infect the Bartholin and Skene glands, the urethra, and ascend into the endometrium and fallopian tube to cause upper reproductive tract infection (Microbiology and Pathogenesis).

DIAGNOSIS

Neisseria gonorrhoeae is a gram-negative coccobacillus that invades columnar and transitional epithelial cells, becoming intracellular. For this reason, the vaginal epithelium is not involved. For gonococcal identification, NAATs are available, and ideal specimens are recovered from the endocervix. These tests have replaced culture in most laboratories. However, these noncultural tests are not FDA-cleared for diagnostic identification of rectal or pharyngeal disease.

All patients tested for gonorrhea should be tested for other sexually transmitted infections, and sexual contacts should be evaluated or referred for evaluation and treatment. Abstinence should be practiced until therapy is completed and until they and their sexual partners have resolution of symptoms.

TREATMENT

Recommendations for single-dose therapy of uncomplicated cervical, urethral, or rectal infection by the CDC is outlined in Table 3-19. Uncomplicated gonococcal pharyngeal infections can be treated with either the ceftriaxone or ciprofloxacin regimens listed. Quinolone-resistant gonococci are increasing in the U.S., particularly the east and west coast. Those strains are common in Europe, the Middle East, the Pacific, and Asia. For that reason, the CDC has advised against quinolone use in California, Hawaii, and for travelers who have been to the listed countries. Test-of-cure cultures are not necessary; however, re-infection is common. Some recommend retesting 3 months following initial therapy.

Chlamydia trachomatis

This organism is the second most prevalent of the sexually transmitted disease species recovered in the United States, and its highest prevalence is found in individuals younger than 25 years. Since many with this organism are asymptomatic, annual screening of sexually active women younger than 25 years and those at risk is recommended (see Table 1-2).

SYMPTOMS

This obligate intracellular parasite is dependent on host cells for survival (Lymphogranuloma Venereum (LGV)). It causes columnar epithelial infection. Thus presenting symptoms reflect endocervical glandular infection, with resultant mucopurulent discharge or

endocervical secretions. If infected, the endocervical tissue is commonly edematous and hyperemic. Urethritis is another lower genital tract infection that can develop, and dysuria is prominent.

DIAGNOSIS

Microscopic inspection of secretions following a saline preparation typically reveals 20 or more leukocytes per high-power field. More specifically, culture, NAAT, and enzyme-linked immunosorbent assay (ELISA) are available for endocervical specimens. Alternatively, a combined gonococcal and chlamydial test is widely used. If *C trachomatis* is diagnosed or suspected, then screening for other STDs is indicated. Moreover, sexual partner(s) should be counseled, tested, and treated or referred for evaluation.

TREATMENT

Recommended therapy for *C trachomatis* infection is described in Table 3-20. Azithromycin has the obvious therapeutic compliance advantage of allowing clinicians to observe ingestion at the time of diagnosis. Following treatment, retesting is not recommended if symptoms resolve. To prevent further infection, abstinence is recommended until a woman and her partner(s) are asymptomatic.

PATHOGENS CAUSING MASS LESIONS

External Genital Warts

These lesions are created from productive infection with the human papillomavirus (HPV), and a fuller discussion of the pathophysiology of this virus is found in Chapter 29, Human Papillomavirus. Genital warts display differing morphologies, and appearances range from flat papules to the classic verrucous, exophytic lesions, termed *condyloma acuminata* (Fig. 3-17) (Beutner, 1998). Involved tissues vary and external genital warts may develop at sites in the lower reproductive tract, urethra, anus, or mouth. They are typically diagnosed by clinical inspection, and biopsy is not required unless co-existing neoplasia is suspected (Beutner, 1998; Wiley, 2002). Similarly, HPV serotyping is not required for routine diagnosis.

FIGURE 3-17

TREATMENT

Condyloma acuminata may remain unchanged or spontaneously resolve, and the effect of treatment on future viral transmission is unclear (Centers for Disease Control and Prevention, 2006). However, many women prefer removal, and lesions can be destroyed with sharp or electrosurgical excision, cryotherapy, or laser ablation. In addition, very large, bulky lesions may be managed with cavitational ultrasonic surgical aspiration (see Chap. 40, Cavitational Ultrasonic Surgical Aspiration).

Alternatively, 5-percent imiquimod cream (Aldara, 3M, St. Paul, MN) is a patient-applied immunomodulatory topical treatment for genital warts. This agent induces macrophages to secrete several cytokines, and of these, interferon-γ is probably the most important. For genital wart clearance, this cytokine stimulates a cell-mediated immune response against HPV (Scheinfeld, 2006). Other topical agents may be applied for treatment of warts (Table 3-21). Of these, podophyllin is an antimitotic agent available in a 10- to 25-percent tincture of benzoin solution and disrupts viral activity by inducing local tissue necrosis. A biologically active extract of podophyllin, *podofilox,* also termed *podophyllotoxin,* is available in a 0.5-percent solution or gel (Condylox, Watson Pharma, San Antonio, TX), which can be self-applied by the patient. Alternatively, trichloroacetic acid and bichloroacetic acid are proteolytic agents and are applied serially to warts by clinicians. Intralesion injection of interferon is an effective treatment for warts (Eron, 1986). However, because of high cost and painful and inconvenient administration, this therapy is not recommended as a primary modality and is best reserved for recalcitrant cases (Centers for Disease Control and Prevention, 2006).

Table 3-21 Recommended Treatment of External Genital Warts
Patient-applied:
Podofilox 0.5% solution or gel. Patients should apply podofilox solution with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. This cycle may be repeated, as necessary, for up to four cycles. The total wart area treated should not exceed 10 cm^2 , and the total volume of podofilox should be limited to 0.5 mL per day.
or
Imiquimod 5% cream. Patients should apply imiquimod cream once daily at bedtime, three times a week for up to 16 weeks. The treatment area should be washed with soap and water 6 to 10 hours after the application.
Provider-administered:
Cryotherapy with liquid nitrogen or cryoprobe. Repeat applications every 1 to 2 weeks.
or
Podophyllin resin 10 to 25 percent in a compound tincture of benzoin. A small amount should be applied to each wart and allowed to air dry. The treatment can be repeated weekly, if necessary. Application should be limited to <0.5 mL of podophyllin or an area of <10 cm^2 of warts per session. No open lesions or wounds should exist in the area to which treatment is administered. Some specialists suggest through washing 1 to 4 hours after application to reduce local irritation.
or
Trichloroacetic acid (TCA) or **Bichloroacetic acid** (BCA) 80 to 90 percent. A small amount should be applied only to the warts and allowed to dry, at which time a white "frosting" develops. This treatment can be repeated weekly if necessary. If an excess amount of acid is applied, the treated area should be powdered with talc, sodium bicarbonate (i.e., baking soda), or liquid soap preparations to remove unreacted acid.
or
Surgical removal either by tangential scissor excision, tangential shave excision, curettage, or electrosurgery.
Alternative regimens:
Intralesional interferon
or
Laser surgery

From Centers for Disease Control and Prevention, 2006, with permission.

Of therapy choices, no data suggest the superiority of one treatment. Thus in general, treatment should be selected based on clinical circumstances and patient and provider preferences.

Molluscum Contagiosum

The molluscum contagiosum virus is a DNA virus that is transmitted by intimate contact. The host response to viral invasion is papular with central umbilication, giving a characteristic appearance (Fig. 3-18). It may be single or multiple and is commonly seen on the vulva, vagina, thighs, and/or buttocks.

FIGURE 3-18

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph of molluscum contagiosum. Flesh-colored, dome-shaped papules with central umbilication are noted. *(From Wolff, 2005a, with permission.)*

These lesions are typically diagnosed by visual inspection alone. However, material from a lesion can be collected on a swab, applied to a slide, and submitted to a laboratory for diagnostic staining with Giemsa, Gram, or Wright stains. Molluscum bodies, large intracytoplasmic structures, are diagnostic.

Most lesions spontaneously regress over 6 to 12 months. If removal is preferred, lesions may be treated by cryotherapy, electrosurgical needle coagulation, or sharp needle-tip curettage of a lesion's umbilicated center. Alternatively, topical application of agents used in the treatment of genital warts may also be applied effectively to treat molluscum contagiosum (see Table 3-21).

Scabies

ETIOLOGY

Sarcoptes scabiei infect skin and result in an intensely pruritic rash. The mite causing this infection is crab-shaped, and the female digs into the skin and remains there for approximately 30 days, elongating her burrow. Several eggs are laid daily and begin hatching after 3 to 4 days (Fig. 3-19). The baby mites furrow their own burrows, becoming reproductive adults in approximately 10 days. The number of adult mites present on an affected patient averages a dozen, although theoretically there could be hundreds. Mites crawl at a rate of two and a half centimeters per minute, and sexual transmission is the most likely cause of initial infection, although it can be seen in household contacts.

Photomicrograph of burrow with *Sarcoptes scabiei.* A mite is seen at the end of a burrow **(far right)** with seven eggs and smaller fecal particles. *(From Wolff, 2005b, with permission.)*

DIAGNOSIS

A delayed-type 4 hypersensitivity reaction to the mites, eggs, and feces develops and results in erythematous papules, vesicles, or nodules in association with skin burrows. Secondary infection, however, may develop and hide these burrows. Most common infection sites include the hands, wrist, elbows, groin, and ankles. Itching is the predominant symptom in these areas.

Burrows are thin elevated tracks in the skin measuring 5 to 10 mm in length. Definitive testing requires scraping across the burrow with a scalpel blade and mixing these fragments in immersion oil on a microscope slide. Identification of mites, eggs, egg fragments, or fecal pellets is diagnostic.

TREATMENT

Once diagnosed, 1-percent lindane cream (Kwell) is a commonly used agent. A thin layer should be applied from the neck downward with special attention to pruritic areas and the hands, feet, and genital regions. It is recommended that all family members be treated with the exception of pregnant or lactating women and children younger than 2 years. Treatment is effective within 4 hours. Eight to 12 hours after application, a shower or bath should be taken to remove the medication. Only one application is necessary, and bed linens and recently worn clothing should be washed to prevent reinfection.

For pregnant women and young children, 10-percent crotamiton cream or lotion (Eurax, Bristol-Myers Squibb, Princeton, NJ) is recommended since it is nontoxic. It should be applied nightly for two nights, and a bath or shower should not be taken for 48 hours. Another treatment regimen is with a 5-percent permethrin cream (Elimite), which is effective after a single application. It should be washed off in 8 to 12 hours and is safe in children older than 2 months and in pregnant women.

An antihistamine will help reduce pruritus, which can also be treated with a hydrocortisone-containing cream in adults or with emollients or lubricating agents in infants. If these lesions become infected, antibiotic therapy may be necessary.

Pediculosis

ETIOLOGY

Lice are small ectoparasites that measure approximately one millimeter in length (Fig. 3-20). Three species infest humans and include the body louse (*Pediculus humanus*), the crab louse (*Phthirus pubis*), and the head louse (*Pediculus humanus capitis*). Lice attach to the base of human hair with claws, and it is this claw's diameter that determines the infestation site. For this reason, the crab louse is found on pubic hair and other hair of similar diameter, such as axillary and facial hair, including eyelashes and eyebrows.

FIGURE 3-20

Phthirus pubis. **A.** Pubic lice are seen attached to hair. In addition, nits are seen as dark dots adhered to pubic hair. *(From Long, 1990, with permission.)* **B.** Photomicrograph of *Phthirus pubis.* Claw-like legs are ideally suited for clinging to hair shafts. *(From Birnbaum, 2002, with permission.)*

Lice depend on frequent human blood meals, and pubic lice may travel up to 10 centimeters in search of darkness and a new attachment site for blood. They leave voluntarily if the victim becomes febrile, dies, or if there is close contact with another human. Accordingly, pubic lice usually are sexually transmitted, whereas head and body lice may be transmitted by sharing personal objects such as combs, brushes, and clothing.

SYMPTOMS AND DIAGNOSIS

The main symptom from louse attachment and biting is pruritus. Scratching results in erythema and inflammation, which increases blood supply to the area. Patients may develop pyoderma and fever if secondarily infected. As is true for mites, the number of lice populating a patient averages a dozen.

Each female adult pubic louse lays approximately four eggs a day, which are glued to the base of hairs. Incubation is about 1 month. Their attached eggs, termed *nits,* can be seen attached to the hair shaft away from the skin line as hair growth progresses (see Fig. 3-20). These nits usually require a magnifying glass for identification. Moreover, suspicious flecks on pubic hair or flecks in clothing can be examined microscopically to see the characteristic louse. Other family members should be evaluated, as should sexual contacts.

TREATMENT

Pediculicides kill not only adult lice, but also the eggs. A single application is usually effective, but a second application is recommended within 7 to 10 days to kill new hatches. Nonprescription shampoos contain pyrethrins and piperonyl butoxide and should remain on the skin for at least 1 hour. These include brand names such as Rid, Lice-enz, R&C, Pronto, and A-200 shampoos.

Alternatively, 1-percent lindane shampoo may also be recommended only for pubic lice treatment. Creams and lotions are reserved for scabies. The treatment is applied to the pubic region for 4 minutes and then rinsed. This compound is percutaneously absorbed through excoriated skin, and seizures have been reported if applied too frequently or not washed off.

Eyelash and eyebrow treatment is problematic. These areas are best treated by applying petrolatum (Vaseline, Unilever, Englewood Cliffs, NJ) with a cotton swab at night and washing it off in the morning. Underclothing, bedding, and other infested clothing should be washed and sprayed with Lysol disinfectant (Reckitt Benckiser, Parsippany, NJ). Water temperature greater than 125Â°F is required to kill lice.

In spite of treatment, pruritus may continue and may be relieved by oral antihistamines, anti-inflammatory cream or ointment, or both. The patient should be re-evaluated after 1 week to document louse eradication. The sexually transmitted nature of this disease should be discussed and patients offered testing for other sexually transmitted infections.

URINARY TRACT INFECTIONS

Symptomatic acute bacterial urinary tract infections (UTIs) are among the most common bacterial infections treated by clinicians. It is estimated that there are more than 8 million office visits per year for these infections in the United States. Cystitis accounts for most of these, whereas more than 100,000 patients are admitted to a hospital annually for acute pyelonephritis treatment. Due to the high incidence of UTI, the Infectious Diseases Society of America has developed guidelines for its treatment (Warren, 1999).

Pathogenesis

Because of their pelvic anatomy, women have many more UTIs than men. Bacteria ascending from the colonized urethra enter the bladder and perhaps the kidneys. The short length of the female urethra allows easier access by bacteria to the bladder. Contributing to contamination, the warm moist vulva and rectum are both in close proximity. Similarly, sexual intercourse increases bladder inoculation.

Infections result from the interaction between bacteria and host. Bacterial virulence factors are important, as they enhance colonization and invasion of the lower and upper urinary tract. The principal virulence factors are increased adherence to either vaginal or uroepithelial cells and hemolysin production. The bacterial species most frequently recovered from infected urine culture is *Escherichia coli* (Table 3-22).

Once within the bladder, bacteria may ascend within the ureters, enhanced by vesicourethral reflux, into the renal pelvis and cause upper tract infection. The renal parenchyma also can be infected by blood-borne organisms, especially during staphylococcal bacteremia. *Mycobacterium tuberculosis* gains access to the kidney through this route and also perhaps by ascension.

Uncomplicated Acute Bacterial Cystitis

DIAGNOSIS

The most frequent presenting complaints in otherwise healthy, immunocompetent nonpregnant women are dysuria, frequency, urgency, and incontinence.

Studies conducted by the National Institutes of Health (NIH), Mayo Clinic, and others have shown that most patients can be treated with a short course of antibiotics without examination, urinalysis, or urine culture for an isolated episode of acute *uncomplicated* bacterial cystitis (Table 3-23). It must be emphasized that a patient in this category can always be seen if she prefers. In addition, women should be instructed on clinical changes that warrant further attention such as fever 100.4Â°C and persistence or recurrence of hematuria, dysuria, and frequency despite treatment.

Table 3-23 Exclusions from 'Uncomplicated' Cystitis
Symptoms of vaginitis (vaginal discharge/vulvar irritation)
Persisting symptoms despite >3 days of treatment of urinary tract infection
Abdominal and/or pelvic pain, nausea, vomiting
Documented temperature above 38Â°C (100.5Â°F)
Recent hospital or nursing home discharge
Documented urologic abnormalities
Recent UTI or urologic surgery
Postmenopausal hematuria
Symptoms >7 days
Immunosuppression
Pregnancy
Diabetes

Women with these exclusions require evaluation to exclude other potential causes of their symptoms. For example, hematuria in a postmenopausal woman may reflect cervical, uterine, or colonic bleeding evident at the time of urination, rather than upper and lower urinary tract infection. Similarly, burning with urination may indicate vulvitis.

Complicated or Recurrent Cystitis

Up to as many as 50 percent of women who suffer an uncomplicated acute bacterial episode of cystitis will have another infection within a year. Up to 5 percent have recurring symptoms soon after treatment. When symptoms develop in such women, the likelihood that a true infection is present is greater than 80 percent.

DIAGNOSIS

Thus, for selected women with complicated or recurrent infections or with persistent or new symptoms during treatment, urinalysis and urine culture are mandatory. For a culture specimen to be informative, it must be accurately collected. A "clean catch" midstream voided urine specimen is usually sufficient. It is mandatory that a patient understands the reasons for and the steps associated with urine specimen collection, which are designed to prevent contamination by other bacteria from the vulva, vagina, and/or rectum. More than one bacterial species identified in a urine culture usually indicates specimen collection contamination.

Initially, a patient spreads her labia and wipes the periurethral area from front to back with an antiseptic tissue. With labia spread, she begins urinating but does not collect the initial stream. A sample is then collected into a sterile specimen cup. The specimen cup is sterile and should be handled by the patient in such a way to avoid contamination. After collection, a urine specimen is delivered promptly to the laboratory and should be plated for culture within 2 hours of collection unless it is refrigerated.

Culture

Urine culture allows accurate identification of an inciting pathogen and susceptibility testing of that pathogen to a variety of antibiotics. Significant bacteriuria is most commonly defined as $\geq 10^5$ bacteria (colony-forming units [cfu]) per milliliter of urine. If urine is collected by either suprapubic aspirate or catheterization, colony counts $\geq 10^2$ cfu/mL are diagnostic. Although a bacterial species may be identified preliminarily, a final urine culture report usually is not available for 48 hours. Thus, empiric treatment is

initially begun but modified, as needed, after culture results are available.

Although anaerobic bacteria are part of the vaginal, colonic, and skin flora, they rarely cause UTIs. Hence, urine culture reports do not note anaerobes except in rare instances in which the laboratory should be alerted to and specifically requested to look for an anaerobic species. Fungi can be identified on routine bacteria media and are reported, but are rare causes of acute cystitis.

Culture is the gold standard for identifying the cause of a urinary tract infection, but no laboratory culture techniques help rapidly identify significant bacteriuria. However, there are rapid tests that give an immediate indication of infection and include microscopy, nitrite testing, and leukocyte esterase testing.

Microscopy

Microscopy of a urine specimen allows identification of both pyuria and bacteria. For identification of leukocytes, a specimen should be examined expeditiously because leukocytes deteriorate quickly in urine that has not been appropriately preserved. Standards to define pyuria are inadequate, other than gross counts. Accordingly, the rapid test for leukocyte esterase has become a surrogate for the microscopic WBC count.

Gram staining is a simple, rapid, and sensitive method for detecting a concentration $\geq 10^5$ cfu/mL of a bacterial species. Rapid identification allows appropriate selection of empiric antimicrobial therapy. However, realistically, such testing is typically limited to patients with complicated urinary tract infections or acute pyelonephritis.

Leukocyte Esterase

This test measures esterase enzyme found in urinary leukocytes and enzyme released from poorly preserved specimens. If used alone diagnostically, this test is most beneficial for its high negative predictive value, especially with bacterial colony counts $\geq 10^5$ cfu/mL. If one combines nitrite and leukocyte esterase testing of a clean-catch uncontaminated voided specimen, the specificity of positive tests approaches 100 percent with uropathogen colony counts of $\geq 10^5$ cfu/mL. The negative predictive value is comparable.

However, if these specimens have been contaminated with vaginal or colonic bacteria, this test can be falsely positive in the absence of a uropathogen. *Trichomonas* species also produce esterases. In addition, very concentrated urine or urine with significant proteinuria or glucosuria will decrease the accuracy of this test.

Nitrites

Bacteria metabolically produce nitrites from nitrates. The bacteria in which this is most frequently observed are Enterobacteriaceae, the family of pathogens most commonly responsible for acute UTIs in women. The major drawback of this test is that it does not identify gram-positive pathogens such as staphylococci, streptococci, enterococci, or *Pseudomonas* species. In addition, it ideally requires testing of the *first morning urine specimen,* because more than 4 hours are required for bacteria to convert nitrates to nitrites at levels that are detectable by the test method. As a single test, the specificity of a positive nitrite test is very high with $\geq 10^5$ cfu/mL of a uropathogen. Its negative predictive value is higher than its positive predictive value.

TREATMENT

There have been changes in not only the etiologic pathogens of acute cystitis, but also sensitivities of those pathogens to antibiotic regimens. During the past two decades, there has been an increase in the frequency of infections caused by group B *Streptococcus* and *Klebsiella* species, and a decrease in infections caused by *E coli.* Also in many locations, sensitivity patterns in *E coli* warrant a shift in initial empiric treatment from trimethoprim-sulfamethoxazole to a quinolone for this infection (Table 3-24).

Table 3-24 Treatment of Urinary Tract Infection

Infection Category	**Antimicrobial Regimen**
Uncomplicated cystitis	Orally 3 days

Adopted from Warren 1999, and Fihn, 2003.

If a woman has a sulfa allergy, she can take trimethoprim alone. Treatment courses of any regimen longer than 3 days result in almost twice the number of adverse events, are not more effective, are more costly, and have higher rates of noncompliance. In addition, single-dose therapy has been shown to be less effective than 3-day regimens. Nitrofurantoin regimens are usually 7 days, and are frequently associated with upper GI symptoms.

For significant dysuria, up to 2 days of a bladder analgesic such as over-the-counter phenazopyridine, 200 mg orally up to three times daily, may give significant relief. However, GI upset, yellow-orange strained urine and clothing, and hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are potential side effects.

Many recurrences develop after intercourse, and low-dose postcoital dosing or continuous 3-day regimens are usually effective at preventing infection recurrence. A women with two or more episodes of cystitis within 6 months or three infections within a year should be referred for urologic evaluation of her urinary tract.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is defined as isolation of a specified quantitative count of bacteria in an appropriately collected urine specimen obtained from a person without symptoms or signs referable to urinary infection (Rubin, 1992). In healthy nonpregnant women, the prevalence of this condition increases with age. It is associated with sexual activity, and is more common in diabetics. Moreover, one fourth to one half of elderly women in long-term care facilities have bacteriuria, which is seen primarily in those with chronic neurologic illness and functional impairment.

The Infectious Disease Society of America recommends that nonpregnant premenopausal women not be screened for asymptomatic bacteriuria (Nicolle, 2005). In controlled randomized prospective trials, women randomly given a 1-week course of antibiotic or placebo had similar prevalences of bacteria and incidences of symptomatic infection 1 year after therapy. The same is true for diabetic women, in whom there is evidence of harm with treatment of asymptomatic bacteriuria. Additionally, routine screening is

not recommended for older persons living in the community.

Acute Uncomplicated Pyelonephritis

DIAGNOSIS

This infection may be divided into mild (no nausea or vomiting, normal to slightly elevated blood leukocyte count, and normal to low-grade fever) and severe (vomiting, dehydration, evidence of sepsis, high leukocyte count, and fever). Other symptoms may include those of a lower urinary tract infection and varying degrees of back pain and tenderness to percussion over the region of the kidney(s).

TREATMENT

Traditional therapy for this infection has included hospitalization and intravenous antibiotic treatment for up to 2 weeks. However, more recent studies in young healthy women with normal urinary tracts indicate that 7 to 14 days of oral therapy are sufficient for compliant women with mild infection (see Table 3-24) (Warren, 1999). In one study of more than 50 college women with acute uncomplicated pyelonephritis, resistance to trimethoprim-sulfamethoxazole was 30 percent (Hooton, 1997). Accordingly, an oral fluoroquinolone is recommended treatment unless a pathogen is susceptible to trimethoprim-sulfameth- oxazole. At initial diagnosis, clinicians may also administer a parenteral dose prior to starting oral therapy. Alternatively, if a causative organism is gram-positive, then amoxicillin or amoxicillin/clavulanic acid is recommended.

Hospitalization is warranted for women who display clinical indications at initial evaluation or fail to improve with outpatient therapy.

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) is an infection of the upper reproductive tract organs. Another diagnosis given to this disease is acute salpingitis. Although all may be involved, the organ of importance, with or without abscess formation, is the fallopian tube. Because of difficulty in accurately diagnosing this infection, its true magnitude is unknown. Many women report that they have been treated for PID when they did not have it, and vice versa.

Microbiology and Pathogenesis

The exact microbiologic pathogens in the fallopian tube cannot be known for any given patient. Studies have shown that transvaginal culture of the endocervix, endometrium, and cul-de-sac contents revealed different organisms from each site in the same patient. In laparoscopic studies, cervical pathogens and those recovered from the fallopian tube or cul-de-sac were not identical. For that reason, treatment protocols are designed so that most potential pathogens are covered by antibiotic regimens.

Classic salpingitis is that associated with and secondary to *N gonorrhoeae* (Table 3-25). Another sexually transmitted disease species frequently recovered from acutely symptomatic women is *T vaginalis.* The lower reproductive tract flora in those patients and in women with bacterial vaginosis are those in which anaerobic species predominate. However, Ness and colleagues (2004) and others have shown that bacterial vaginosis is not a risk factor for development of PID. The sexually transmitted disease species commonly recovered from women diagnosed with PID and reported in Scandinavian studies is *C trachomatis.* It does not, however, cause an acute inflammatory response.

Upper tract infection is believed to be caused by bacteria from the lower reproductive tract that ascend into the upper tract. It is assumed that ascension of bacteria into the upper tract is enhanced during menstruation due to loss of endocervical barriers. The gonococcus can cause a direct inflammatory response in the human endocervix, endometrium, and fallopian tube and is one of the true pathogens of human fallopian tube epithelial cells. If normal human fallopian tube cells in cell culture are exposed to potential pathogens such as *E coli, Bacteroides fragilis,* or *Enterococcus faecalis,* no inflammatory response results. If the above bacteria are introduced into a fallopian tube cell culture in which gonococci are present and have caused inflammatory damage, an exaggerated inflammatory response results.

In contrast, with intracellular *C trachomatis,* cell-mediated immune mechanisms may be responsible for resulting tissue injury. Little direct permanent damage results from chlamydial tubal involvement (Patton, 1983). Tubal destruction in women with repeated asymptomatic chlamydia may be the result of a delayed hyperimmune response.

Women with pulmonary tuberculosis can develop salpingitis and endometritis. It is assumed that this pathogen is blood-borne, but ascension may still be a possible route. The fallopian tubes also can be infected by direct extension from inflammatory gastrointestinal disease, especially ruptured abscess, i.e., appendiceal or diverticular.

Diagnosis

Pelvic inflammatory disease can be segregated into "silent" PID and PID. Of these, PID can be further subdivided into acute and chronic.

SILENT PELVIC INFLAMMATORY DISEASE

It is presumed that this condition results from multiple or continuous low-grade infection in asymptomatic women. Silent PID is not a clinical diagnosis. Rather, it is an ultimate diagnosis given to women with tubal-factor infertility who lack a history compatible with upper tract infection. Many of these patients have antibodies to *C trachomatis* and/or *N gonorrhoeae.* At laparoscopy or laparotomy, these patients may have evidence of prior tubal infection such as adhesions, but for the most part the fallopian tubes are grossly normal. Internally, however, there are flattened mucosal folds, extensive deciliation, and secretory epithelial cell degeneration (Patton, 1989).

ACUTE PELVIC INFLAMMATORY DISEASE

Criteria for Diagnosis of Acute Disease

In women who are symptomatic, symptoms develop during or following menstruation. The most recent recommended diagnostic criteria presented by the CDC (2006) are for sexually active women at risk for STDs who have pelvic or lower abdominal pain and other etiologies are not feasible. Their diagnosis should be PID if they have uterine tenderness, adnexal tenderness, or cervical motion tenderness. One or more of the following enhances diagnostic specificity: (1) oral temperature >38.3Â°C (101.6Â°F), (2) mucopurulent cervical or vaginal discharge, (3) abundant WBCs on saline microscopy of cervical secretions, (4) elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), and (5) presence of cervical *N gonorrhoeae* or *C trachomatis.*

Symptoms and Physical Findings

Presenting symptoms may include lower abdominal and/or pelvic pain, yellow vaginal discharge, menorrhagia, fever, chills, anorexia, nausea, vomiting, diarrhea, dysmenorrhea, and dyspareunia. Patients also may have infective urinary symptoms. Unfortunately, there is no single symptom or symptom associated with a physical finding that is specific for this diagnosis. Accordingly, other possible sources of acute pelvic pain should be considered (see Table 11-1).

In women with acute PID, leukorrhea or mucopurulent endocervicitis is common and is diagnosed microscopically. In women suspected of having acute PID, endocervical testing for both *N gonorrhoeae* and *C trachomatis* should be performed.

During bimanual pelvic examination, women with acute pelvic inflammatory disease will usually have pelvic organ tenderness. Cervical motion tenderness (CMT) is typically elicited by quickly displacing the cervix laterally with examining vaginal fingers. If a woman has pelvic peritonitis secondary to bacteria and purulent debris that has exuded from the fallopian tubes, this rapid peritoneal movement usually causes a marked pain response. Tapping the cul-de-sac with examining finger(s) will give the examiner similar information. This maneuver usually causes a patient significantly less pain because less inflamed peritoneum is involved.

Abdominal peritonitis may be identified by deep probing and quick release of a hand placed on the abdomen. Alternatively, an examining hand may be positioned with a palm against a woman's mid-abdomen and gently and quickly moved back and forth (shake). This will identify abdominal peritonitis, often with less patient discomfort. In women with PID and peritonitis, usually only the lower abdomen is involved. If all quadrants are involved, suspicion of a ruptured tubo-ovarian abscess should be heightened.

Laparoscopy

In Scandinavian countries, women suspected of having acute PID undergo laparoscopy for diagnosis. Tubal serosal hyperemia, tubal wall edema, and purulent exudate issuing from the fimbriated ends of the fallopian tubes and pooling in the cul-de-sac confirm this diagnosis.

Because of this routine practice, Hadgu and co-workers (1986) assembled criteria that preoperatively clinically predicted acute pelvic inflammatory disease and assessed their validity by the absence or presence of disease at laparoscopy. Criteria included: (1) single status, (2) adnexal mass, (3) age younger than 25 years, (4) temperature >38Â°C, (5) cervical *N gonorrhoeae,* (6) purulent vaginal discharge, and (7) ESR ≥15 mm/hr. The preoperative clinical diagnosis of PID was 97-percent accurate if a woman met all seven criteria. Accordingly, due to the cost of laparoscopy, antimicrobial therapy based on a clinical diagnosis in patients with historical and physical findings suggestive of acute PID is prudent.

Sonography

In women with marked abdominal pain and tenderness, appreciation of upper reproductive tract organs during bimanual examination may be limited. In these patients, vaginal sonography may be used to identify tubo-ovarian abscess or exclude other pathology as the pain source (Figs. 2-15 and 2-16) (Molander, 2001). If sonography does not lead to a clear diagnosis, computed-tomography (CT) scanning may be indicated (Sam, 2002).

Endometrial Biopsy

In women suspected of acute PID, some recommend endometrial biopsy to diagnose endometritis. Polymorphonuclear leukocytes

on the endometrial surface correlate with acute endometritis, whereas plasma cells in the endometrium are found with chronic endometritis. However, women with uterine leiomyomas or endometrial polyps and no PID frequently also have plasma cells present in the endometrium at endometrial biopsy, as do essentially all women in the lower uterine segment. This, in the opinion of many, indicates that in women with mucopurulent secretions, an endometrial biopsy would not provide useful information to alter the diagnosis or therapy (Achilles, 2005).

CHRONIC PELVIC INFLAMMATORY DISEASE

This diagnosis is given to women who describe a history of acute PID and who have pelvic pain. Accuracy of this diagnosis clinically is orders of magnitude less than for acute PID. A hydrosalpinx might qualify as a criterion for this diagnosis (Figs. 9â€“17 and 9â€“18). Realistically, however, it is a histologic diagnosis (chronic inflammation) made by a pathologist. Thus, the clinical utility of this diagnosis is limited.

Treatment

The most beneficial patient outcomes follow early diagnosis and prompt, appropriate therapy. The primary goal of therapy is to eradicate bacteria, relieve symptoms, and prevent sequelae. Tubal damage or occlusion resulting from infection may lead to infertility. Rates following one episode approximate 15 percent; two episodes, 35 percent; and three or more episodes, 75 percent (Westrom, 1975). Also, ectopic pregnancy risk is increased six- to 10-fold and may reach a 10-percent risk for those who conceive. Other sequelae include chronic pelvic pain (15 to 20 percent), recurrent infection (20 to 25 percent), and abscess formation (5 to 15 percent). Unfortunately, women with mild symptoms may remain at home for days or weeks prior to presentation for diagnosis and therapy.

Exactly where a patient should be treated remains controversial. There are proposed criteria that predict better outcome for certain patients with in-hospital parenteral antimicrobial therapy (Table 3-26). However, the high cost of in-hospital treatment prevents routine hospitalization for all women given this diagnosis.

ORAL TREATMENT

In women with a mild to moderate clinical presentation, outpatient treatment and inpatient therapy yield similar results. Clinical treatment with oral therapy is also appropriate for women with HIV infection and PID. These women have the same species recovered compared with non-HIV infected patients and response to therapy is similar.

However, if women have more than moderate disease, they require hospitalization. Dunbar-Jacob and associates (2004) showed that women treated as outpatients took 70 percent of prescribed doses, and for less than 50 percent of their outpatient treatment

days. If patients are to be treated as outpatients, an initial parenteral dose may be beneficial. If women do not respond to oral therapy within 72 hours, re-evaluation is indicated and parenteral therapy should be initiated either as an inpatient or as an outpatient if home nursing care is available. This assumes that the diagnosis was confirmed at re-evaluation.

Specific treatment recommendations from the CDC are found in Table 3-27. As mentioned earlier (Treatment), if patients have been recently to California, Hawaii, the east coast, or other areas with increased quinolone-resistant strains of *N gonorrhoeae,* quinolones should not be used. Anaerobes are believed by some to play an important role in upper tract infection and should be treated. Although prospective clinical trials have established that quinolones alone have excellent cure rates, anaerobes are not predictably covered. Hence, metronidazole may be added to improve anaerobic coverage. If patients have BV or trichomoniasis, then metronidazole addition is required, although perhaps not for 14 days.

PARENTERAL TREATMENT

Any woman who has criteria as outlined in Table 3-26 should be hospitalized for parenteral treatment for at least 24 hours.

Following this, if home parenteral treatment is available, this is a reasonable option. Alternatively, if a woman will be appropriately treated by one of the oral regimens in Table 3-27, then she can be discharged on those medications.

Recommendations for parenteral antibiotic treatment of pelvic inflammatory disease are found in Table 3-28. Of these antibiotics, oral and parenteral routes of doxycycline have almost identical bioavailability, but parenteral doxycycline is caustic to veins. Many prospective clinical trials have shown that either of the listed cephalosporins alone, without doxycycline, will bring a clinical cure. For that reason, doxycycline administration could be reserved until the patient can take oral medication. The recommendation is to continue parenteral therapy until 24 hours after the patient clinically improves and the oral doxycycline should continue to complete 14 days of therapy. Alternatively, if the primary reason for providing doxycycline is to eradicate chlamydia, a 1-g oral dose of azithromycin while the patient is in the hospital will also achieve that goal.

For women with an abscess, some also administer oral clindamycin (450 mg every 6 hours) or metronidazole (as shown) to complete therapy. Treatment of a patient with an abscess should include parenteral antimicrobial therapy until the patient has been afebrile for at least 24 hours, preferably 48 to 72 hours. Surgery is rarely required. Although older recommendations for abscess

include hysterectomy and adenexectomy, current antibiotics obviate most surgery. If antibiotic treatment fails, then abscess drainage alone typically will suffice. Often this is possible percutaneously by a radiologist with CT guidance and should be considered initially for abscesses larger than 8 cm.

POSTOPERATIVE INFECTION

Clinical Significance and Risks

Operative site infections continue to account for many hospital-acquired infections. Development of a postoperative infection may result in doubling or even tripling of a predicted hospital stay, resulting in significant patient morbidity and increased health care costs. Risks for postoperative infection are varied and include patient and surgical factors (Table 3-29). Of these, the degree of wound contamination at the time of surgery plays an important role in these infections.

Table 3-29 Risk Factors for Postoperative Surgical Site Infections
Excessive blood loss
Preoperative anemia
Lower socioeconomic status
Immunocompromised patient
Recent operative site surgery
Obesity (abdominal hysterectomy)
Younger age (vaginal hysterectomy)
Older age (abdominal hysterectomy)
Prolonged surgical procedure (>3.5 hours)
Foreign body placement (catheter, drain, etc.)

Because most gynecologic surgical procedures are elective, a gynecologist has time to decrease microbial inoculum. Thus, BV, trichomonal vaginitis, cervicitis, and active urinary tract or respiratory infection ideally are treated prior to surgery.

Wound Classification

Since 1964, surgical wounds have been classified according to the degree of bacterial contamination of the operative site at the time of surgery. As the number of operative site bacteria (inoculum) increases, so too does the postoperative infection rate.

CLEAN WOUNDS

Surgeries that are elective; that are performed for nontraumatic surgical indications; are without operative site inflammation; and avoid the respiratory, alimentary, and genitourinary tracts are included in this category. No break occurs in surgical technique. Thus, most laparoscopic and adnexal surgeries are considered to be in this category, and strictly speaking, supracervical hysterectomy could also be added. Without prophylaxis, infection rates range from 1 to 5 percent. Prophylactic antimicrobial administration *does not* decrease infection rates following these procedures and should not be administered.

CLEAN CONTAMINATED WOUNDS

These are surgical wounds in which the respiratory, gastrointestinal, genital, or urinary tract is entered under controlled conditions and without unusual bacterial contamination. Criteria further define that there can be no break in surgical technique. Infection rates range from 5 to 15 percent. This group encompasses most gynecologic procedures including total hysterectomy, cervical

conization, and dilatation and curettage (D&C). Of these, hysterectomy is the gynecologic procedure most frequently followed by a surgical site infection. These procedures are usually elective, and only hysterectomy requires antimicrobial prophylaxis to reduce postoperative infection rates.

CONTAMINATED WOUNDS

Classic cases in this category include open, fresh, accidental wounds; operations with major breaks in sterile technique or gross GI spillage; and incisions in which acute, nonpurulent inflammation is encountered (Mangram, 1999). Infection rates approximate 10 to 25 percent. For this reason, a minimum of 24 hours of perioperative antimicrobial administration is required, and delayed wound closure may be selected. Laparoscopy or laparotomy for acute salpingitis should be included in this category.

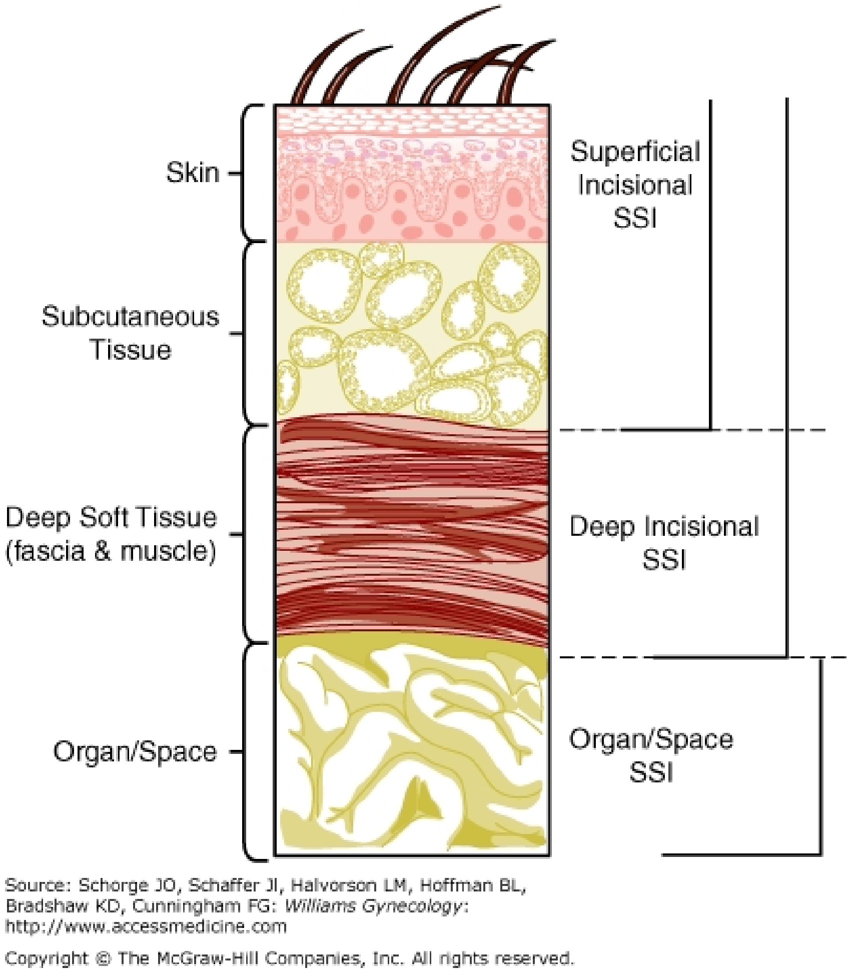
DIRTY WOUNDS

These are typically old traumatic wounds or those that involve existing clinical infection or perforated viscera. These operative sites are clinically infected at the time of surgery, and infection rates range from 30 to 100 percent. Accordingly, therapeutic antimicrobial therapy is required.

Surgical Site Infection Classification

In 1992, the CDC provided definitions of hospital-acquired surgical site infections (SSIs). These were modified by Horan and others during the same year. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) currently is emphasizing this morbidity during their hospital accreditation process. Thus, hospitals are more attentive to infection rates and to the rates of individual surgeons. In classifying SSIs, there are two categories, incisional and organ space (Fig. 3-21). The incisional group is further subdivided into superficial and deep classes. Criteria for each category are detailed in Table 3-30.

FIGURE 3-21



Anatomy and classification of surgical site infections (SSI). *(Redrawn from Mangram, 1999.)*

Table 3-30 Criteria for Defining Surgical Site Infections
Superficial incisional
Involves only superficial tissues
Develops within 30 days of surgical procedure
Features:
Purulent drainage or bacteria in culture of tissue or fluid
Signs or symptoms
Tenderness or pain
Heat or redness
Localized swelling
Required opening of superficial incision

Superficial incision infection diagnosis made by surgeon
Stitch abscesses are not included in this category
Vaginal cuff cellulitis should be included here (see Fig. 3-22)
Deep incisional
Abdominal wall muscle and fascia are involved
Develops within 30 days of surgical procedure
Features:
Purulent drainage from deep incision, not organ or space component, of surgical site
Deep incision that spontaneously dehisces or is deliberately opened by a surgeon in a patient who has at least one of the following signs or symptoms:
Temperature ≥ 38Â°C (100.4Â°F)
Localized pain or tenderness
Abscess or other infection found by reoperation, histopathology, or radiology
Diagnosis made by surgeon
Parametritis (pelvic cellulitis) should be included in this category (see Fig. 3-23)
Organ/space
Develops within 30 days of the surgical procedure
Features:
Purulent drainage from a drain placed through a stab wound into the organ/space
Bacteria recovered from tissue or fluid in that organ/space
Abscess found by reoperation, histopathology, or radiology
Diagnosis made by surgeon

Modified from Mangram, 1999, with permission.

ORGAN/SPACE

These infections develop in spaces or organs other than that opened by the original incision or manipulated during the surgical procedure. Specific sites include the vaginal cuff, urinary tract, and intra-abdominal sites. Of note, vaginal cuff infections are considered in the superficial incisional class and parametritis is classified as a deep incisional infection (Figs. 3-22 and 3-23). In contrast, pelvic infections such as adnexal infection, pelvic abscess, or infected pelvic hematoma fall into the category of organ/space infection (Figs. 3-24 and 3-25).

This is an abscess or infected hematoma that is extraperitoneal and cephalad to the vaginal margins. An adnexal abscess or intraperitoneal abscess should be included, though these are rare.

Diagnosis

FEBRILE MORBIDITY

The most frequently used definition for febrile morbidity is an oral temperature of ≥38Â°C on two or more occasions, 4 or more hours apart, and 24 or more hours following surgery. This condition is seen most frequently after hysterectomy, particularly abdominal hysterectomy; usually is not associated with other symptoms or signs of infection; and does not require antimicrobial therapy! It has been reported in up to 40 percent of women following abdominal and almost 30 percent of women after vaginal hysterectomy with antimicrobial prophylaxis. It resolves without antibiotic treatment in the absence of other symptoms or signs of infection.

A remote nonsurgical site may also serve as an origin of fever. These may include pulmonary complications, intravenous (IV) site phlebitis, and urinary tract infection. Thus, women who develop recurrent temperature elevation require a thorough history and a careful physical examination by the surgeon, seeking not only surgical, but also nonsurgical causes (see Fig. 39-6).

PAIN

Operative site pain (incisional, lower abdominal, pelvic, and/or lower back) following surgery is normal. Patients who develop an operative site infection report increasing pain in the SSI area, and increasing tenderness is present on physical examination. For most gynecologic patients with pelvic infection, this is deep lower abdominal and/or pelvic pain. The most common infection sites requiring antimicrobial therapy are the parametria and the vaginal surgical margin. Pelvic abscess or infected pelvic hematoma is least common, and pain is central. Pain associated with abdominal incision infection is localized to the incision.

PHYSICAL EXAMINATION

Abdominal palpation is an integral part of SSI diagnosis in gynecology. Avoiding an abdominal incision if present, a surgeon gently and deeply palpates the lower abdomen over the surgical site following hysterectomy and normally elicits patient discomfort. Tenderness does not mean an acute surgical abdomen or infection. In the immediate postoperative period, this tenderness is expected, and decreases quickly. Women who develop pelvic cellulitis or cuff cellulitis will have increasing tenderness at gentle depression of the lower abdominal wall over the infected area. Tenderness may be bilateral, but more commonly is more marked on one side than the other. Peritoneal signs are not present. Cellulitis, whether it involves the parametria, adnexa, or vaginal cuff, is not associated with a mass.

In the absence of increasing lower abdominal pain and tenderness, a bimanual examination is not necessary for asymptomatic temperature elevation. However, with a combination of fever, increasing tenderness, and new-onset pain, gentle bimanual examination is required to accurately identify the infection site and to exclude or diagnose a mass. Speculum examination usually is not required, and findings are similar with or without an existing infection. As is true for routine pelvic examination, most information at bimanual examination is obtained from the vaginal fingers.

If a patient is too tender to allow adequate examination, vaginal sonography is indicated. Bowel function is usually not altered by soft tissue cellulitis, but may be by pelvic abscess or infected pelvic hematoma.

CULTURE

Pelvic infections following hysterectomy are polymicrobial, and for that reason, it is difficult to identify true pathogens. Research has demonstrated that bacteria recovered transvaginally from the pelvis of infected and clinically uninfected women are similar. Accordingly, routine transvaginal culturing of women with cuff or pelvic cellulitis does not add useful information. Moreover, a surgeon should not wait for culture results before starting empiric broad-spectrum antibiotic therapy. However, if initial therapy is partially effective or unsuccessful, then a culture will more predictably identify pathogen(s) since therapy will have eradicated other species. The antibiotic regimen should be changed, and culture results may direct this change.

In contrast, abscess or infected hematoma fluid should be cultured since those species are less likely to be vaginal contaminants. The same is true for any fluid or purulent material present in an abdominal incision.

Specific Infections

VAGINAL CUFF CELLULITIS

Essentially all women develop this infection at the vaginal surgical margin after hysterectomy. Normal response to healing is characterized by small-vessel engorgement, which results in erythema and heat. There is vascular stasis with endothelial leakage resulting in interstitial edema, which causes induration. This area is tender, microscopic evaluation of a wet prep reveals numerous WBCs, and purulent discharge is seen in the vagina. This process usually subsides and does not require treatment.

The few women who do require treatment are usually those who present after hospital discharge with mild, but increasing, new-onset lower abdominal pain and have a yellowish vaginal discharge. Findings are as above, but the vaginal cuff is more tender than anticipated at this interval from the initial surgical procedure. Oral antimicrobial therapy with a single broad-spectrum agent is appropriate (Table 3-31). A patient should be re-evaluated in several days to assess therapeutic efficacy. This may be completed by

phone or with an examination if necessary.

Regimen	Dose
Single-agent intravenous	
Cephalosporin	
Cefoxitin	2 g every 6 hours
Cefotetan	2 g every 12 hours
Cefotaxime	1 to 2 g every 8 hours
Penicillin with or without β-lactamase inhibitor	
Piperacillin	4 g every 6 hours
Piperacillin/tazobactam	3.375 g every 6 hours
Ampicillin/sulbactam	3 g every 6 hours
Ticarcillin/clavulanate	3.1 g every 4 to 6 hours
Carbapenems	
Imipenem/cilastatin	500 mg every 8 hours
Meropenem	500 mg every 8 hours
Ertapenem	1 g once daily
Combination agent intravenous	
Metronidazole	Loading dose 15 mg/kg; maintenance dose 7.5 mg/kg every 6 hours
Ampicillin	2 g every 6 hours
Gentamicin	3 to 5 mg/kg once daily
Clindamycin	900 mg every 8 hours
Gentamicin	As above
with or without Ampicillin	As above
Oral agents	
Amoxicillin/clavulanate	875 mg twice daily
Levofloxacin	500 mg once daily
Clindamycin	300 mg every 6 hours

Metronidazole	500 mg every 6 hours

PELVIC CELLULITIS

This is the most common infection following either vaginal or abdominal hysterectomy. It develops when host humoral and cellular defense mechanisms, combined with preoperative antibiotic prophylaxis, cannot overcome the bacterial inoculum and inflammatory process at the vaginal surgical margin. The inflammatory process spreads into the parametrial region(s) resulting in lower abdominal pain, regional tenderness, and temperature elevation. This usually happens during the late second or third postoperative day. There are no peritoneal signs, and bowel and urinary function are normal. There may be anorexia.

Since patients are discharged on perhaps their first or second postoperative day following vaginal hysterectomy, these patients may be at home before onset of their symptoms, requiring a return visit for evaluation and diagnosis. Hospitalization and treatment with an intravenous broad-spectrum antibiotic regimen is indicated until a patient has been afebrile for 24 to 48 hours, at which time she may be discharged home (see Table 3-31).

Most patients requiring hospitalization for intravenous antibiotic therapy are discharged with an oral antimicrobial prescription. Single-agent therapeutic regimens have been shown in prospective randomized trials to be as effective as combination-agent regimens. These infections are polymicrobial, and the regimen selected must have coverage for gram-positive and gram-negative aerobic and anaerobic bacteria.

ADNEXAL INFECTION

This infection is uncommon and presents almost exactly as does pelvic cellulitis. The difference is in the location of tenderness during bimanual pelvic examination. The cuff and parametrial areas are not usually tender, but the adnexa are areas of tenderness. This infection also may develop after tubal ligation, surgical therapy for ectopic pregnancy, or other adnexal surgery. Empiric antibiotic regimens are identical to those for pelvic cellulitis (see Table 3-31).

OVARIAN ABSCESS/INFECTED PELVIC HEMATOMA

A rare but life-threatening complication following primarily vaginal hysterectomy is ovarian abscess. Presumably, with this infection, surgery is performed in the late proliferative phase of an ovulatory menstrual cycle, and ovaries are in close proximity to the vaginal surgical margin. As expected, physiologic cuff cellulitis develops normally, but when ovulation occurs, bacteria in the area gain access to the ovulation site and the corpus luteum. The corpus luteum many times becomes hemorrhagic, and the blood in this functional cyst is a perfect medium for bacterial growth.

Patients in whom this develops have essentially a normal postoperative course until about 10 days following surgery. At this time they experience, acute unilateral lower abdominal pain, which then becomes generalized. These symptoms reflect rupture of their abscess or infected hematoma and development of generalized abdominal peritonitis. Sepsis commonly follows, and this is a true gynecologic emergency. Exploratory laparotomy is necessary immediately, with preoperative and continued administration of broad-spectrum antimicrobials, evacuation of the abscess, and removal of the affected ovary and adjacent fallopian tube.

Similarly, women rarely may develop a tubo-ovarian abscess (usually a pyosalpinx) identical to that seen as an end result of an episode of acute pelvic inflammatory disease. This process can be managed medically with intravenous antimicrobials, and surgery is usually not required unless rupture follows. Combination antimicrobial therapy should be continued until a woman has been afebrile for 48 to 72 hours.

PELVIC ABSCESS/INFECTED PELVIC HEMATOMA

Pelvic abscess not involving an adnexal structure is also uncommon. Decades ago, prior to routine administration of antimicrobial prophylaxis, vaginal surgical margins were typically sutured in a fashion to create an *open cuff* . This method eliminated space between the vagina and peritoneum. If not performed, this space allowed collection of up to 200 mL of blood, serum, and/or lymph between the vaginal margin and the peritoneum following hysterectomy. These fluids provide an excellent milieu for the overgrowth of bacteria inoculated into the adjacent tissues during the surgical procedure. As a result, prior to the initiation of antimicrobial prophylaxis, pelvic infection rates following hysterectomy were as high as 60 percent, and up to 10 percent of these infections were

cuff abscesses. However, administration of preoperative prophylactic antibiotics predictability decreases these infection rates following hysterectomy regardless of whether an open or closed cuff is created.

Signs and symptoms of pelvic abscess are more central, and a mass is discernible centrally. Transvaginal sonography can accurately characterize the dimensions of this abscess/infected hematoma. Hospital readmission for therapy is necessary. Combination-agent antimicrobial therapy is indicated. Additionally, opening the vaginal surgical margin, if possible, to allow drainage will aid treatment and accelerate patient response. This can usually be done in a treatment room early, avoiding return to the operating room. If necessary, these can be drained with sonographic transvaginal guidance or in the operating room. These abscesses or infected hematomas usually remain confined to the extraperitoneal space, and a patient does not develop peritonitis. Some patients may develop diarrhea due to the proximity of the rectum, which is usually adjacent to the infected space.

This infection is also one that does not present until after a patient is discharged from the hospital. Combination intravenous antibiotics should be administered until a woman has been afebrile 48 to 72 hours.

ABDOMINAL INCISION INFECTION

The superficial and easily accessible location of this infection aids its diagnosis. Although abdominal incision infection may develop alone or with pelvic infection following abdominal hysterectomy, it develops uncommonly after other gynecologic procedures. Unlike pelvic infection, the incidence of this infection is not altered by antimicrobial prophylaxis. Risk factors include obesity, occlusive drapes, excessive use of electrosurgical coagulation, passive drains, and inflammation in the skin through which the incision was made.

Abdominal incisions are usually the most uncomfortable following gynecologic surgery, but pain decreases daily. Erythema and heat are the first physical signs of this infection, which is usually diagnosed on the fourth or fifth postoperative dayâ€"again after discharge from the hospital. A hematoma or seroma may develop in the abdominal wall incision without infection. If these collections are large, opening of the incision and evacuation to prevent infection in those fluids is warranted. Similarly, pus requires incision opening to ensure an intact fascia, as should be done with seromas or hematomas.

Drainage and local care are usually the basis of successful therapy for abdominal incision infection, hematoma, or seroma. Wet to dry dressings stimulate fibroblastic proliferation and development of healthy granulation tissue. Moistening the dry dressing prior to its removal will ease removal and decrease patient discomfort. Several solutions can be used with mechanical dÃ©bridement of wound margins, if necessary. At this stage secondary closure can be considered. Importantly, wounds should be irrigated with normal saline to remove dÃ©briding solutions, as they are caustic to healing tissues. If there is soft tissue cellulitis adjacent to the incision, antimicrobial therapy is a requirement. Wound vacuum-assisted closure (VAC) devices (Wound VAC, Kinetic Concepts International, San Antonio, TX) are available for more serious or larger wound areas that are slow to respond (see Chap. 39, Negative-Pressure Wound Therapy).

TOXIC SHOCK SYNDROME

This condition, caused by a toxin (TSS toxin-1) produced by *Staphylococcus aureus,* appears about 2 days following surgery or onset of menstruation. Menstrual-associated appearance was initially associated with high-absorbency tampons. The vagina must be colonized by a toxigenic staphylococcal strain, and the patient must lack the specific antibody that can block the super- antigen.

The classic nonmenstrual and menstrual toxic shock syndromes have identical clinical symptoms, physical findings, and laboratory results. Women complain of fever, malaise, and diarrhea. In addition to minimal signs of wound infection, if postoperative, a patient has conjunctival and pharyngeal hyperemia without purulence. The tongue is usually reddened, and there is erythema of the skin on the trunk that is neither painful nor pruritic. Temperatures are usually above 38.8Â°C and orthostatic hypotension or shock may be present. This syndrome results from host cytokines released in response to superantigenic properties of the toxin. The criteria for this diagnosis are presented in Table 3-32.

Table 3-32 Criteria for Diagnosis of Toxic Shock Syndrome
Major criteria
Hypotension
Orthostatic syncope
Systolic BP <90 mm Hg for adults
Diffuse macular erythroderma
Temperature ≥38.8ÂºC
Late skin desquamation, particularly on the hands, palms, and soles of feet (1 to 2 weeks later)
Minor criteria (organ system involvement)
Gastrointestinal: diarrhea or vomiting
Mucous membranes: oral, pharyngeal, conjunctival, and/or vaginal erythema
Muscular: myalgia or creatinine phosphokinase level greater than twice normal
Renal: BUN and creatinine greater than twice normal or >5 WBCs/HPF in urine, without concurrent UTI
Hematologic: platelet count <100,000 per mm^3
Hepatic: SGOT, SGPT, and/or bilirubin levels greater than twice normal
Central nervous system: altered consciousness or disorientation without focal localizing signs

BP = blood pressure; BUN = blood urea nitrogen; HPF = high-powered field; SGOT = serum glutamic oxaloacetic transaminase; SGPT = serum glutamic pyruvic transaminase; UTI = urinary tract infection; WBC = white blood cell.

The wound, if present, should be treated as any other wound. It should be cultured to confirm the presence of *S aureus.* However, other cultures (e.g., blood, throat, and cerebrospinal fluid) will be negative. To meet the strict criteria of the diagnosis, a woman must have all major and at least three minor criteria. If this is suspected early and therapy is initiated, the complete syndrome may not develop.

Although it is important to treat with a specific antistaphylococcal antibiotic, the hallmark of therapy is entire system support with large volumes of intravenous fluids and electrolytes to replace massive body fluid losses from diarrhea, capillary leakage, and insensible loss. These patients may develop significant edema and are best managed in an intensive care unit. Even with appropriate management, the death rate has been reported to be as high as 5 percent because of subsequent acute respiratory distress syndrome (ARDS), disseminated intravascular coagulopathy (DIC), or hypotension unresponsive to therapy with resultant myocardial failure. This syndrome may also follow gynecologic surgical procedures such as D&C, hysterectomy, urethral suspension, and tubal ligation.

Serologies for Rocky Mountain spotted fever, measles, and leptospirosis must be negative. Viral infection and group A streptococci can cause a similar presentation.

NECROTIZING FASCIITIS

Although described in the 1870s, it was not named until 1952 by a Parkland Hospital surgeon (Wilson, 1952). It has had various names, including hospital gangrene, acute dermal gangrene, acute streptococcal gangrene, Meleney gangrene, gangrenous

erysipelas, and necrotizing erysipelas. Risk factors for this postoperative incision infection are age over 50, arteriosclerotic heart disease, diabetes mellitus, obesity, debilitating disease, smoking, and previous radiation therapy, all of which are associated with decreased tissue perfusion. Also, it has been reported following tubal sterilization, in a suprapubic catheter site after hysterectomy, in vulvar tissues of diabetics, and even without surgery, especially in vulvar infections of obese diabetic women. Only about 20 percent of cases follow surgery, the majority developing after minor injuries or insect bites. Bacteria recovered from women with this infection are similar to those recovered from any postoperative gynecologic infection site, namely predominantly *E coli, E faecalis, Bacteroides, Peptostreptococcus, S aureus,* groups A and B hemolytic streptococci, and other Enterobacteriaceae.

Although this postoperative superficial incisional infection begins like any other postoperative infection with pain and erythema, the hallmark for its identification is subcutaneous and superficial fascial necrosis, manifested by excessive tissue edema in adjacent areas (Table 3-33). Blisters or bullae form in tissue that has become avascular and is discolored. There is usually a thin gray transudate. Tissue destruction is far more extensive than is evident by surface examination. The skin will slip over underlying tissue, and if incised, due to the lack of vascularity, there will be no bleeding. Severe systemic toxicity may develop. It is beneficial to get radiographs of the infected area prior to treatment to exclude gas in the tissue produced by *Clostridium perfringens* or other clostridial species. The presence of these bacteria is often associated with myonecrosis.

Table 3-33 Criteria for Diagnosis of Necrotizing Fasciitis
Microvascular thrombosis without major vessel occlusion
Extensive necrosis of superficial fascia undermining normal skin
Absence of clostridia in wound and/or blood cultures
No muscle involvement
Intensive WBC infiltrate in necrotic subcutaneous tissue
Moderate-to-severe systemic toxic reaction

WBC = white blood cell.

Although it is important to administer antibiotics, the cornerstone of treatment is prompt recognition with immediate surgical removal of the devitalized tissue down to tissue that bleeds appropriately. This may result in excision of large areas of tissue, leaving significant disfigurement. However, postponing surgery while waiting for antimicrobial activity will only increase the volume of tissue death. Early fatality rates for patients with this infection approached 80 percent according to Stone and Martin (1972).

Wounds are left open and treated as wound infections as described earlier with local hydrotherapy or a wound VAC. Assistance from a general surgeon for potential grafting is often necessary.

BENIGN DISORDERS OF THE LOWER REPRODUCTIVE TRACT: INTRODUCTION

The lower reproductive tractâ€"comprised by the vulva, vagina, and cervixâ€"harbors a wide spectrum of benign, premalignant, and malignant disease. Lesion characteristics commonly overlap, and differentiating between normal variants, benign disease, and potentially serious lesions can be challenging. However, benign lesions of the lower reproductive tract are common, and in the practice of gynecology, mastery of their identification and treatment is essential.

VULVAR LESIONS

Vulvar skin is more permeable than surrounding tissues because of differences in structure, hydration, occlusion, and susceptibility to friction (Farage, 2004). As a result, pathology involving the vulva is common, although estimates of incidence are difficult because of patient underreporting and clinician misdiagnosis. Lesions may result from infection, trauma, neoplasia, or immune responses. As a result, symptoms vary and may include pain, pruritus, dyspareunia, bleeding, and discharge. Effective therapies are available for most disease, yet embarrassment and fear may prove to be significant roadblocks to care for many women.

Nonneoplasic Vulvar Dermatoses

Classification of nonneoplastic disorders of the vulvar skin and mucosa have undergone multiple iterations over the last 30 years in an attempt to accurately categorize clinical and histologic findings. The International Society for the Study of Vulvovaginal Disease (ISSVD) first convened in 1970 as an international, multidisciplinary society dedicated to the study of vulvar disease. In 1987, the ISSVD adopted nomenclature based on both histopathologic and gross changes (Table 4-1). For those diseases that may display variable histologic appearances, multiple vulvar biopsies may be required for correct classification.

SQUAMOUS CELL HYPERPLASIA (LICHEN SIMPLEX CHRONICUS)

Chronic trauma secondary to rubbing or scratching elicits lichenification, a protective response of the involved skin. Thickening of both the epidermis (acanthosis) and the stratum corneum (hyperkeratosis) produces the characteristic palpable thickening with exaggerated skin margins. Most lesions of squamous cell hyperplasia are symmetric bilaterally and may extend beyond the labia majora.

Behavioral risk factors for developing squamous cell hyperplasia include persistent rubbing, chronic scrubbing, and development of a chronic itch-scratch cycle (Lynch, 2004). There are numerous triggering factors, including chemical substances contained within hygiene products and topical medicines (Virgili, 2003).

Physical examination of affected areas reveals excoriations in a background of erythematous skin. Correlation of these physical findings with historical information is typically sufficient to reach the diagnosis. Treatment involves halting the itch-scratch cycle. Topical steroid ointments help to reduce inflammation, whereas lubricants and sitz baths help to restore the skin's barrier function. If symptoms fail to resolve within 1 to 3 weeks, biopsy is indicated to exclude other pathology.

LICHEN SCLEROSUS

Since the earliest reported cases in the literature in the late 1800s, lichen sclerosus has been plagued with confusing terminology all referring to the same processâ€”lichen sclerosus et atrophicus, lichen albus, Briesky kraurosis vulvae, and balanitis xerotica obliterans. Friedrich (1976) first suggested that the histologic process was more than atrophy. As a result, the ISSVD formally adopted the term *lichen sclerosus* to define this chronic inflammatory skin condition that predominantly affects the anogenital skin (Moyal-Barracco, 2004).

Incidence

Lichen sclerosus classically presents in postmenopausal women, although cases are found in premenopausal women, children, and even men (ages 30 to 50). In a referral dermatologic clinic, lichen sclerosus was found in between 1:300 and 1:1000 cases with a tendency towards Caucasians (Wallace, 1971). Others estimate an incidence of childhood lichen sclerosus to be 1:900 (see Chap. 14, Lichen Sclerosus) (Powell, 2001).

Pathophysiology

Although the cause of lichen sclerosus remains unknown, genetic, infectious, hormonal, and autoimmune etiologies have been suggested. Approximately 20 to 30 percent of patients with lichen sclerosus have other autoimmune processes, in particular thyroid disease and diabetes mellitus (Goolamali, 1974; Meyrick Thomas, 1988). In addition, nearly 75 percent of patients have circulating autoantibodies (Harrington, 1981).

Hormonal differences have been another investigated source. Friedrich and Kalra (1984) compared serum androgen and estrogen levels in women with lichen sclerosus with those in age-matched controls. Both dihydrotestosterone (DHT) and androstenedione levels were significantly lower in women with lichen sclerosus, and a reduced local activity of 5?-reductase was implicated.

Because of this study, 2-percent testosterone ointment was touted to improve lichen sclerosus and lichen sclerosus with squamous cell hyperplasia (Friedrich, 1985; Kaufman, 1974). Unfortunately, these results have not been replicated in subsequent studies and testosterone is no longer recommended in the treatment of lichen sclerosus (Bornstein, 1998; Cattaneo, 1996; Sideri, 1994).

Despite this variety of proposed mechanisms, the cause of lichen sclerosus appears to be multifactoral.

Risks

Despite being classified as a nonneoplastic dermatosis, patients with lichen sclerosus have demonstrated an increased risk of vulvar malignancy. Biopsy-proven cellular atypia typically precedes a diagnosis of invasive squamous cell carcinoma. Thus, women with lichen sclerosus should be examined every 4 to 6 months and new or changing lesions should be biopsied.

Symptoms of Lichen Sclerosus

Despite some women being completely asymptomatic, most women with lichen sclerosus will complain of anogenital symptoms. The hallmark symptom, although nonspecific, is vulvar pruritus and is thought to result from inflammation of local terminal nerve fibers. Pruritus-induced scratching creates a vicious cycle leading to excoriations and further thickening of the vulvar skin. Later symptoms can include dyspareunia due to architectural changes, tenesmus, dysuria, and anorgasmia.

Differential Diagnosis

Although clinical findings may suggest lichen sclerosus, histologic confirmation aids in proper choice of therapy. Lichen planus and vulvar intraepithelial neoplasia (VIN) can both be excluded histologically on biopsy. Although vitiligo produces a depigmented

pattern similar to lichen sclerosus, vulvar architecture remains intact with vitiligo. Estrogen-deficient atrophy will lead to thinning of the epidermis with labial adhesions and associated dyspareunia. In the absence of improvement with local estrogen therapy, a vulvar biopsy will help identify underlying disease. In children, lichen sclerosus poses the need to identify possible prior sexual assault. Sexual abuse and trauma have been suggested as possible provocateurs of lichen sclerosus in genetically predisposed individuals (Ridley, 1993; Weiss, 2002).

Diagnosis

The characteristic clinical picture and histologic confirmation typically lead to the diagnosis. Unfortunately in long-standing cases, histology may be nonspecific, and clinical judgment with close surveillance should guide treatment plans.

Physical Examination

As mentioned earlier, vulvar and perianal involvement is seen in nearly 85 percent of cases. The typical white, atrophic papules may coalesce into porcelain-white plaques and lead to labia minora regression, clitoral concealment, urethral obstruction, and introital stenosis. Over time a lesion may spread to the perineum and anus and form a figure-8 or hourglass shape (Fig. 4-1) (Clark, 1967).

Laboratory Testing

A consistent relationship between lichen sclerosus and autoimmune disorders such as Graves disease, type 1 and 2 diabetes mellitus, systemic lupus erythematosus, and achlorhydria, with or without pernicious anemia, have been reported in patients with lichen sclerosus (Bor, 1969; Helm, 1991; Kahana, 1985; Poskitt, 1993). Accordingly, concurrent testing for these disorders is indicated if other suggestive findings are present.

Vulvar Biopsy

Thickened white plaques on the vulva should typically prompt vulvar biopsy to exclude preinvasive and invasive lesions.

To perform the biopsy, the items shown in Fig. 4-2 should be assembled. The biopsy site is first cleaned with an antimicrobial wash and is infiltrated with a 1- or 2-percent lidocaine solution. Biopsy is performed with a Keyes punch biopsy instrument. This tool has an open, circular, sharp-edged tip that is designed to remove a vertical core of tissue when pressed against the skin. Once the dermis has been cut, fine dissecting scissors are used to undermine the circular biopsy and free it.

Keyes punches are available in a variety of diameters, ranging from 2 to 6 mm, and size selection is typically based on lesion dimensions. Following excision, bleeding may be controlled with direct pressure, silver nitrate stick, or Monsel solution.

Treatment

In the absence of curative solutions, the treatment goals for lichen sclerosus include alleviation of symptoms, prevention of progressive anatomic changes, and early detection of malignant transformation. A multidisciplinary approach including patient education, behavior modification, psychological support, and pharmacologic therapy in a dedicated vulvar clinic yield optimal results.

Patient Education

Vulvar hygiene is one of the cornerstones of lichen sclerosus management (Table 4-2). Modifications focus on minimizing both chemical and pressure irritation of the skin.

Table 4-2 Vulvar Hygiene Recommendations
Avoid using gels, scented bath products, moisturizing wipes, and soaps, as they may contain irritants
Use aqueous creams to clean the vulva
Avoid using a harsh washcloth to clean the vulva
Dab the vulva gently to dry
Avoid wearing tight fitting pants
White cotton underwear is preferred
Avoid washing undergarments in commercial washing detergents. Wash and rinse these items separately. Consider using a multirinse process with cold water to remove any remaining detergent
Consider wearing skirts and no underwear when in the house and at night to avoid friction and aid drying

In addition, the chronicity of lichen sclerosus and lack of a cure naturally elicits an array of emotions. International support groups dedicated to lichen sclerosus, such as that found at www.lichensclerosus.org , may offer much needed psychological support.

Topical Corticosteroids

First-line therapy for lichen sclerosus is ultrapotent topical corticosteroid preparations such as 0.05-percent clobetasol propionate (Temovate, GlaxoSmithKline, Philadelphia, PA), or 0.05-percent halobetasol propionate (Ultravate, Bristol-Myers Squibb, New York, NY). Ointment formulations are better tolerated due to their minimally allergenic properties, although some practitioners prefer cream-based products (Table 4-3). Despite theoretical risks of pituitary-adrenal axis suppression and iatrogenic Cushing syndrome if used in large doses for extended periods, clobetasol propionate is believed to have effective anti-inflammatory, anti-pruritic, and vasoconstrictive properties (Paslin, 1996).

	Diflorasone 0.05%	Psorcon (cream, ointment)	bid to qid
	Halobetasol propionate 0.05%	Ultravate (cream, ointment)	bid

bid = twice daily; OTC = over the counter; qd = daily; qid = four times daily; tid = three times daily.

One of the earliest prospective trials by Bracco and colleagues (1993) found 0.05-percent clobetasol propionate superior to both topical 2-percent testosterone and 2-percent progesterone. Subsequent series have supported these findings (Cooper, 2004).

Initiation of treatment is recommended within 2 years of symptom onset to prevent significant scarring. The currently recommended dosing schedule by the British Association of Dermatologists is 0.05-percent clobetasol propionate once nightly for 4 weeks, followed by alternating nights for 4 weeks, and finally tapered to twice weekly for 4 weeks. In affected women, after an initial course of therapy, recommendations for maintenance therapy vary and range from use of corticosteroids only as needed, to ongoing twice-weekly therapy.

Premenarchal vulvar lichen sclerosus has also been shown to respond well to topical clobetasol propionate ointment (see Chap. 14, Lichen Sclerosus) (Smith, 2001). Shorter courses of therapy (2 to 4 weeks) are suggested, and longer courses are reserved for resistant cases.

Intralesional Corticosteroids

One study of eight patients evaluated the efficacy of once-monthly intralesional infiltration of 25 to 30 mg of triamcinolone hexacetonide equally divided bilaterally for a total of 3 months. Severity scores decreased in all categories including symptoms,

gross appearance, and histopathologic findings (Mazdisnian, 1999).

Topical Estrogen

Estrogen therapy is indicated for atrophic changes such as pruritus, epidermal thinning, labial fusion, and dyspareunia. Topical estrogen therapy, however, is not recommended as primary therapy for lichen sclerosus.

Retinoids

Topical tretinoin reduces hyperkeratosis, improves dysplastic changes, stimulates collagen and glycosaminoglycan synthesis, and induces local angiogenesis (Eichner, 1992; Kligman, 1986a, 1986b; Varani, 1989). Virgili and colleagues (1995) evaluated the effects of topical 0.025-percent tretinoin (Retin-A, Ortho Dermatological, Skillman, NJ; Avita, Mylan Pharmaceuticals, Morgantown, WV) applied once daily, five days a week for 1 year. Complete remission of symptoms was seen in more than 75 percent of women. However, more than one-quarter of patients experienced skin irritation, which is common with retinoids (see Chap. 17, Topical Retinoids) (Virgili, 1995).

Tacrolimus

Tacrolimus, (Protopic, Astellas Pharma, Deerfield, IL), a topical calcineurin inhibitor indicated for moderate to severe eczema, has been an agent of recent interest. The drug exerts its action by diminishing antigen-specific T-cell activities and associated proinflammatory cytokine production. Assmann (2003) reported successful treatment of vulvar lichen sclerosus using 0.1-percent tacrolimus twice daily. An advantage of tacrolimus compared with corticosteroids is a theoretical avoidance of atrophic changes since collagen synthesis is unaffected (Assmann, 2003; Kunstfeld, 2003). However, in the face of recent U.S. Food and Drug Administration (FDA) concerns regarding its link to a variety of cancers, clinicians should exercise caution when prescribing such medications for extended use (U.S. Food and Drug Administration, 2006).

Photodynamic Therapy

Investigators have evaluated the effects of phototherapy after pretreatment using 5-aminolevulinic acid in one small series of 12 postmenopausal women with advanced lichen sclerosus. Significant reductions in patient symptoms with continued improvement for up to 9 months were noted (Hillemanns, 1999).

Surgery

Surgical intervention should be reserved for cases of malignancy or significant postinflammatory sequelae. For example, Rouzier and colleagues (2002) described marked improvements in dyspareunia and quality of sexual intercourse if perineoplasty was performed in the face of introital stenosis (Section 41-9, Vestibulectomy). A modified Fenton procedure, which is resection of the posterior fourchette, is an option for patients with scarring at this site. Finally, clitoral adhesions can be surgically dissected to free the hood from the glans. Re-agglutination can be averted using an adhesion barrier such as Surgicel (Ethicon, Piscataway, NJ) in combination with nightly application of ultrapotent topical steroid ointment (Breech, 2000).

Other Dermatoses

INFLAMMATORY

Contact Dermatitis

A primary irritant or an allergic substrate can lead to inflammation of vulvar skin that is termed *contact dermatitis* (Fig. 4-3). This condition is common and in unexplained cases of vulvar pruritus and inflammation, irritant contact dermatitis is diagnosed in as many as 54 percent of patients (Fischer, 1996).

FIGURE 4-3

Vulvar contact dermatitis. *(From Hewitt, 1991, with permission.)*

Irritant contact dermatitis classically presents as immediate burning and stinging upon exposure to an offending agent. In contrast, patients with *allergic contact dermatitis* experience a delayed onset and an intermittent course of pruritus and localized erythema, edema, and vesicles or bullae (Margesson, 2004). A detailed history will aid in differentiating between the two related yet separate entities. Inquiry regarding new hygiene routines, personal care products, douches, contraceptive methods, topical medications, or perfumes may help identify a new source of alcohols, antiseptics, or surfactants (Table 4-4) (Crone, 2000; Fisher, 1973; Marren, 1992).

With allergic contact dermatitis, patch testing may aid in identifying a responsible allergen(s). Associated conditions, such as candidiasis, psoriasis, squamous cell hyperplasia, seborrheic dermatitis, and squamous cell carcinoma can be excluded through appropriate use of biopsy and cultures.

Treatments for both entities involves removal of the offending agent and/or practice, restoration of the natural protective skin barrier, reduction of inflammation, and avoidance of scratching (Table 4-5) (Farage, 2004; Margesson, 2004).

Table 4-5 Treatment Algorithm for Vulvar Contact Dermatitis
1. Stop offending agents and/or practices
2. Correct vulvar skin barrier function
a. Sitz bath twice daily with plain water
b. Application of plain petrolatum
3. Treat any underlying infection
a. Oral antifungal therapy
b. Oral antibiotic administration
4. Reduce inflammation
a. Topical steroids twice daily for 1 to 3 weeks
i. 0.05% clobatesol propionate ointment
ii. 0.1% triamcinolone ointment
b. Systemic steroids for severe irritation
5. Break the itch-scratch cycle
a. Cool packs (no ice packs, as these may injure skin)
b. Plain, cold yogurt on a sanitary napkin for 5 to 10 minutes
c. Consider an SSRI (sertraline 50 to 100 mg) or an antihistamine (hydroxyzine 25 to 100 mg)

SSRI = selective serotonin-reuptake inhibitors.

Intertrigo

Friction between moist opposed skin surfaces produces this chronic condition. Although most commonly seen in the inner thigh aspect of the genitocrural folds, skin changes can also be found in the inguinal and intergluteal regions. Secondary bacterial and fungal infections may complicate the disease process.

The initial erythematous phase, if untreated, can progress to intense inflammation with erosions, exudate, fissuring, maceration, and crusting (Mistiaen, 2004). Subsequent hyperpigmentation and verrucous changes may appear. Symptoms typically include burning and itching.

Treatment entails the use of drying agents such as cornstarch and application of mild topical corticosteroids in the face of inflammation. If skin changes do not respond, then seborrheic dermatitis, psoriasis, atopic dermatitis, pemphigus vegetans, or even scabies should be considered. If superinfection with bacteria or yeast develops, appropriate culture-based therapy is warranted.

To prevent recurrent outbreaks, obese patients are encouraged to lose weight if possible. Other preventive recommendations include wearing light, loose clothing made of natural fibers (Janniger, 2005).

Atopic Eczema

Classically presenting in the first 5 years of life, atopic dermatitis presents as a severely pruritic dermatitis that follows a chronic, relapsing course. Scaly patches with fissuring are evident on examination. Atopic eczema affects 10 to 20 percent of children in the United States, and these individuals may later develop allergic rhinitis and asthma (Spergel, 2003).

Topical corticosteroids and less commonly, immunomodulators, such as tacrolimus, can be used to control flares (Leung, 2004). In the presence of dry skin, local hydration using emollients and bath oil can offer relief.

Psoriasis

Approximately 1 to 2 percent of the United States population is affected by psoriasis, a condition characterized by thickened, red areas of skin covered with silvery scales on extensor surfaces (Fig. 4-4).

Over the last decade, insight into T-cellâ€"mediated pathogenesis has revolutionized the understanding of this disease (Chamian, 2004). It is felt that type 1 T-cellâ€"mediated inflammatory reactions in the skin are linked with keratinocyte hyperproliferation (Lebwohl, 2003; Zhou, 2003). This research has formed the conceptual framework for T-cellâ€"targeted biologic immunoregulators. Alefacept (Amevive, Astellas Pharma, Astellas Pharma, Deerfield, IL), efalizumab (Raptiva, Genentech, South San Francisco, CA), and infliximab (Remicade, Centocor, Horsham, PA) are approved by the FDA for treatment of psoriasis (Ritchlin, 2006).

Psoriasis can be exacerbated by nervous stress and menses with remission experienced during summer months and in pregnancy. Pruritus may be minimal or absent, and psoriasis is often diagnosed by skin findings alone.

Several treatments are available for psoriasis, and those recalcitrant to topical corticosteroids are best managed by a

dermatologist. Topical corticosteroids are widely used for their rapid onset of action and effectiveness. Vitamin D analogues such as calcipotriene (Dovonex, Warner Chilcott, Rockaway, NJ), though similar in efficacy to potent corticosteroids, are associated with local irritation, which is seen in more than 20 percent of patients (Smith, 2006). Phototherapy with ultraviolet B light and photochemotherapy (psoralen plus ultraviolet A light, PUVA) offer short-term relief, but long-term treatment plans require a multidisciplinary team approach (Griffiths, 2000). Newer biologic agents such as efalizumab, alefacept, and infliximab, lack data on long-term safety and efficacy (Smith, 2005).

LICHEN PLANUS

Incidence and Etiology

Lichen planus, an uncommon disease that involves both cutaneous and mucosal surfaces, equally affects men and women between age 30 and 60 years (Mann, 1991). Although much is unknown about the etiology of lichen planus, it is believed to be related to T-cellâ€"related autoimmunity to basal keratinocytes (Goldstein, 2005).

Diagnosis

Women typically complain of chronic vaginal discharge with intense pruritus, dyspareunia, and postcoital bleeding. On physical examination, papules classically seen with lichen planus are violaceous, flat-topped, shiny polygons most commonly present on flexor surfaces of the extremities, trunk, or buccal mucosa (Fig. 4-5) (Goldstein, 2005; Zellis, 1996). Additionally, white striae (Wickham striae) are frequently found in conjunction with the papules, and nail dystrophy may be noted.

FIGURE 4-5

Vulvar lichen planus can present as one of three variants: (1) erosive lichen planus, (2) papulosquamous lichen planus, and (3)

hypertrophic lichen planus. Table 4-6 summarizes the most common mimickers of lichen planus. Lichenoid drug-induced lesions have also been implicated (Table 4-7).

Table 4-6 Differential Diagnosis of Lichen Planus

Class of Lichen Planus	Mimicking Condition	Key Features of Mimicking Condition
Erosive lichen planus	Lichen sclerosus	No vaginal involvement; confirmed by histology
	Pemphigoid vulgaris or benign mucous membrane pemphigoid	Shallow erosive ulcerations with rare vaginal involvement; immunofluorescent histology will confirm (Note: biopsy normal adjacent epithelium)
	BehÃ§et disease	No vaginal involvement; will have ocular involvement; inflammation is perivascular
	Plasma cell vulvitis	Rare; no oral lesions
	Erythema multiforme major/Systemic symptoms	Stephen-Johnson syndrome
	Desquamative inflammatory vaginitis	Vaginal discharge will have elevated pH, sheets of white cells, and parabasal cells
Papulosquamous lichen planus	Molluscum contagiosum	Biopsy confirmation
	Genital warts	Biopsy confirmation
Hypertropic lichen planus	Squamous cell carcinoma	Biopsy confirmation

Women with a genital lesion suspicious for lichen planus require a thorough dermatologic survey to seek extragenital lesions and vice versa (Belfiore, 2007). Nearly one quarter of women with oral lesions will have vulvovaginal involvement, and most with erosive vulvovaginal lichen planus will have oral involvement (Pelisse, 1989).

Treatment of Vulvar Lichen Planus

Of the three lichen planus variants, erosive lichen planus is the most difficult to treat. Pharmacologic therapy remains first-line therapy for this condition. Additional treatment includes improving vulvar hygiene, providing psychological support, and discontinuing medications associated with lichenoid changes.

Cooper and Wojnarowska (2006) prospectively evaluated the clinical course of 114 women with erosive lichen planus treated with ultrapotent topical corticosteroids. Despite more than 70 percent of women exhibiting good response to twice-daily therapy used for 3 months followed by maintenance therapy, only 9 percent achieved complete remission of erosive signs. Alternatively, more than 90 percent of women treated with a preparation containing 0.05-percent clobetasol butyrate, 3 percent oxytetracycline, and 100,000 U/g nystatin were symptom free during initial treatment. Antibiotics are used often used for dermatoses because of their anti-inflammatory and antimicrobial effects.

Other agents shown to be beneficial in small case series include systemic corticosteroids, topical tacrolimus ointment, topical cyclosporine, and oral retinoids (Eisen, 1990; Hersle, 1982; Lozada-Nur, 1997; Morrison, 2002; Pelisse, 1989).

Treatment of Nonvulvar Cutaneous Lichen Planus

Laurberg and co-workers (1991) performed a placebo-controlled trial comparing acitretin, 30 mg orally daily (Soriatane, Connetics, Palo Alto, CA) with placebo in 65 patients and found significant improvement in nearly 65 percent of patients. Acitretin is a retinoid administered daily orally. Alternatively, unpublished experience describes symptom improvement using topical corticosteroids (Cribier, 1998; Oliver, 1993).

Treatment of Vaginal Lichen Planus

Anderson and colleagues (2002) found vaginal corticosteroid suppositories of hydrocortisone 25 mg twice daily with a tapering dose to maintain symptom relief has been shown to offer symptomatic and clinical improvement in more than 75 percent of women. Combining local corticosteroid therapy with vaginal dilators may help restore coital function in patients with moderate vaginal synechiae. Surgical adhesiolysis is a last resort.

Fox-Fordyce Disease

Intensely pruritic, discrete, dome-shaped, papular lesions confined to the apocrine sweat gland openings in reproductive-aged women is known as Fox-Fordyce disease. Keratotic plugs in the upper hair follicles leading to obstruction and rupture is felt to be one of the pathophysiologic features of this disease. The mechanism behind its hormonal and emotional exacerbations remains unclear, but women frequently complain of intense axillary or vulvar pruritus before and during menses and after an emotional event. Topical corticosteroids, antibiotics, ultraviolet phototherapy, topical tretinoin, and even oral contraceptives have been used with variable results (Feldmann, 1992; Giacobetti, 1979; Tkach, 1979).

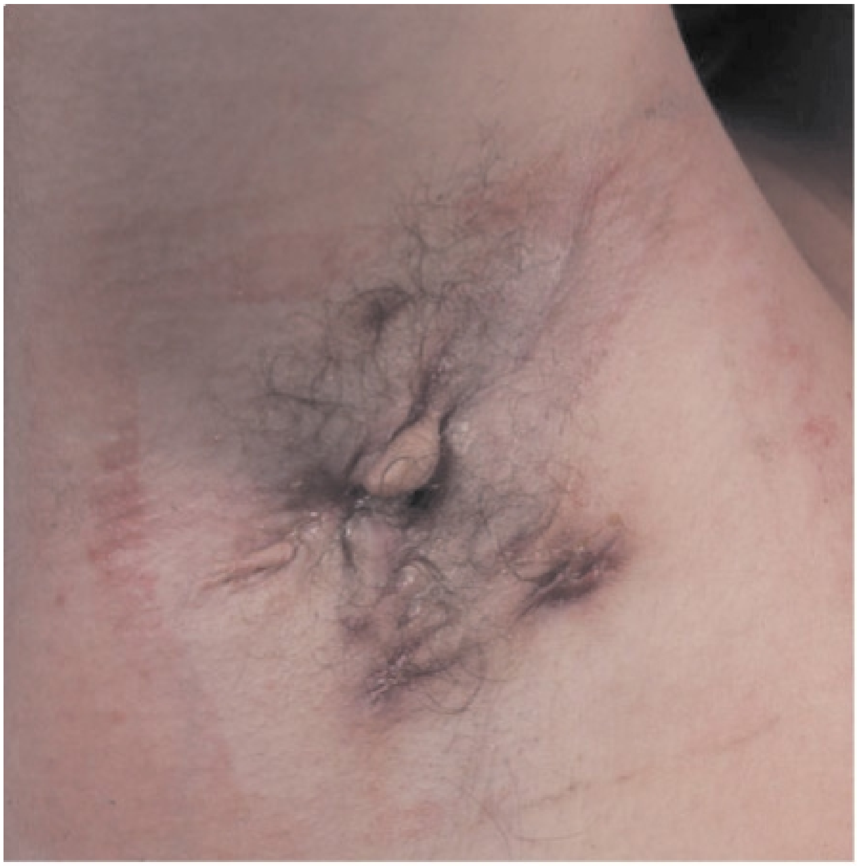
Hidradenitis Suppurativa

Within intertriginous areas, recurrent papular lesions that involve apocrine gland-bearing follicular epithelium typify hidradenitis suppurativa. Little is known about this disease that predominantly affects women (Parks, 1997). Over one quarter of patients will relate a family history of disease, and some authors speculate an autosomal dominant inheritance pattern (der Werth, 2000). Although Mortimer and colleagues (1986) found higher plasma concentrations of androgens in women with hidradenitis suppurativa, others have been unable to verify those findings (Barth, 1996). Bacterial superinfection with *Staphylococcus aureus* and coagulase-negative staphylococci is common but appears to be independent of the actual disease process (Brook, 1999;

Jemec, 1996).

In otherwise healthy women, hidradenitis suppurativa evolves as an insidious discomfort followed by papule or nodule formation (Fig. 4-6). Over time, the process recurs with coalescence of nodules to form large abscesses. Rupture and resolution leads to fibrosis and formation of sinus tracts that drain from cutaneous tissues to the skin surface. Scarring and edema of surrounding structures leads to functional limitations and decreased quality of life (der Werth, 2001; Konety, 1996). Biopsy is typically not required for diagnosis.

FIGURE 4-6



Axillary hidradenitis suppurativa. Scarring and intradermal connecting sinuses are common in more severe forms of this disease. *(From Wolff, 2005a, with permission.)*

Treatment of early phases includes systemic antibiotics, topical antiseptics, and warm compresses to help restore the skin barrier. Since superinfection of hidradenitis suppurativa is polymicrobial, aerobic and anaerobic cultures help guide antibiotic selection. Empiric use of clindamycin in conjunction with a quinolone, however, is reasonable. Sawers and colleagues (1986) found the antiandrogen, cyproterone acetate 50 mg, in conjunction with ethinyl estradiol 50 μg, both orally daily, demonstrated benefit.

Infliximab, a monoclonal TNFa antibody, has had favorable results in case report series (Adams, 2003; Sullivan 2003). The specific relationship between TNFa inhibition and the mechanism by which infliximab exerts its clinical effects is unknown. Its potent anti-inflammatory effects are suspected for its efficacy. However, infliximab has been associated with serious side effects when used to treat rheumatoid arthritis, Crohn disease, and psoriasis. Moreover, in case reports describing its use in patients with hidradenitis suppurativa, infusion reaction, infection, allergic reaction, and neuropathy were cited complications, even during short-term use (Fardet, 2007; Fernandez-Vozmediano, 2007). Accordingly, larger prospective studies are needed.

Surgical excision is reserved for severe cases resistant to medical interventions. Prior to surgical removal of involved tissue, the extent and course of all sinus tracts should clearly be traced. Other surgical options include marsupialization of solitary abscesses or CO_2 laser excision of involved epithelium followed by healing by secondary intention (Finley, 1996). Patients should be reminded that postoperative recurrences do develop, and close surveillance is warranted.

Bullous Lesions

ERYTHEMA MULTIFORME MAJOR (STEVENS-JOHNSON SYNDROME)

Since the initial description by Stevens and Johnson in 1922, confusion continues to exist on the classification of bullous skin lesions with mucosal and cutaneous involvement. Stevens-Johnson syndrome or erythema multiforme major (EMM) is an uncommon condition with a mean age of onset of 25 years (Bagot, 1993; Strom, 1991).

Although patients with the HLA-Bw44 antigen are felt to be more susceptible to developing EMM, timing between drug exposure and clinical patterns provides the best correlation (Mondino, 1982). Antibiotics are the most common cause of EMM, followed by analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), psychoepileptics, and agents used to treat gout.

Patients initially present with a typical target lesion described as having three rings: a bright red inner ring, lighter-pink middle ring, and a darker-pink outer ring. A febrile illness with malaise, headaches, and cough predates the dominant finding of skin detachment (Letko, 2005; Power, 1996). Nearly all patients will exhibit some form of mucosal involvement, ranging from oral and ocular erosions to pulmonary, gastrointestinal, or even renal involvement.

Another condition hypothesized to be a variant of the same disease process is toxic epidermal necrolysis (TEN) (Letko, 2005). This condition develops in an older population (mean age between 45 and 60 years) and carries a much higher mortality rate, quoted to be between 10 and 70 percent (Revuz, 1987). Cutaneous and mucosal defects are similar to those of EMM with the key differences being an absence of the characteristic target lesion, but instead an intense erythema that rapidly progresses to epidermolysis (Heimbach, 1987).

Management of both acute EMM and TEN is primarily removal of the offending drug and supportive care to manage the most commonly seen complications: hypovolemia from increased insensible losses, bronchiolitis obliterans, bloody diarrhea, and increased infections due to loss of the skin barrier (Tsunoda, 1990).

PEMPHIGUS VULGARIS

Blistering of the oral cavity and skin are typical of this rare autoimmune disorder that affects individuals aged 40 to 60 years (Bystryn, 2005). Estimated to affect fewer than 5 cases per million annually, this rare disease if untreated is almost always fatal.

Clinically, pemphigus vulgaris usually begins with painful, nonhealing ulcers of the buccal mucosa, although lesions can be found on the labia, palate, and tongue. Lesions are multiple, irregularly shaped, and superficial (Bystryn, 2005). An immunofluorescent assay for tissue-fixed and circulating intracellular antibodies to keratinocyte surface antigens is the most specific diagnostic test (Nisengard, 1975).

Mortality in untreated cases is high and primarily results from infection and metabolic complications. Initial therapy includes systemic corticosteroids (prednisone orally 60 to 80 mg daily), and the milligram dose is increased until new lesions cease formation and established wounds begin healing. Plasmapheresis and intravenous immunoglobulin (IVIG) have been studied and are considered second-line agents (Harman, 2003). Long-term therapy includes gradual discontinuation of systemic medications and transition to topical corticosteroids to suppress new lesions.

Ulcerative Lesions

APHTHOUS ULCERS

Nearly 25 percent of women in the second and third decade of life will experience these self-limited mucosal lesions. Classically found in nonkeratinized oral mucosa, aphthous ulcers may also develop on vulvovaginal surfaces. Lesions are painful and can recur once every few months.

Although the etiology of aphthous ulcers is unknown, some theorize the origin to be immunologically mediated epithelial cell

damage (Rogers, 1997). Other described triggering factors include trauma, malnutrition, infection, and hormonal fluctuation. In addition, deficiencies in vitamin B_{12}, folate, iron, and zinc have been reported to be causative (Torgerson, 2006). Despite the self-limited nature of this process, lesions that persist for more than 14 days can lead to painful scarring (Rogers, 2003).

Treatment for aphthous ulcers diagnosed at the onset of ulceration can be treated with high-potency topical corticosteroids. Systemic corticosteroids taken orally can help decrease inflammation in cases initially resistant to topical corticosteroids. Finally, colchicine, dapsone, and thalidomide have been shown to be effective.

BEHÃ§ET DISEASE

This is a rare, chronic, multisystem inflammatory process that affects patients in their twenties and thirties. This condition is characterized by mucocutaneous lesions with associated ocular and systemic inflammation.

Although the exact etiology of BehÃ§et disease remains unknown, possession of the HLA-B51 allele carries genetic predisposition in some populations. Infectious triggers have been investigated, although a definitive agent has not been identified. In cases with multiorgan involvement, vasculitis with inflammatory damage explains the pathogenic process.

BehÃ§et disease produces lesions that generally heal within 7 to 10 days without major scarring. Nevertheless, associated pain can be debilitating. The process does have a variable course during pregnancy but no adverse maternal or fetal outcomes have been reported (Marsal, 1997). Treatment for lesions is similar to that of aphthous ulcers.

Lesions of Pigmentation

HYPERPIGMENTATION

Several theories explain the spectrum of hyperpigmentation disordersâ€"genetic predisposition, environmental toxins, sequelae of chronic diseases, and drug reactions (Grimes, 2006).

Acanthosis Nigricans

Velvety, brown, poorly marginated plaques located in the flexures, especially the neck, axillae, and genitocrural folds, characterize acanthosis nigricans.

Acanthosis nigricans is a commonly recognized dermatologic complication of obesity, with an incidence estimated up to 75 percent (Hud, 1992; ÃŽosipovitch, 2007). A significant relationship has also been reported between degrees of obesity and concurrent hyperinsulinemia (see Chap. 17, Acanthosis Nigricans) (Garcia-Hidalgo, 1999).

The mechanism behind acanthosis nigricans formation originates with cellular insulin resistance leading to compensatory hyperinsulinemia. Insulin binds to insulin-like growth factor (IGF) receptors in peripheral tissue leading to proliferation of keratinocytes and dermal fibroblasts (Cruz, 1992; Hermanns-Le, 2004).

Treatment includes correction of hyperinsulinemia. Weight loss can ameliorate insulin resistance leading to a reduction in insulin/IGF receptor complexes and subsequent skin lesion improvement. The vitamin D3 analog calcipotriene inhibits proliferation and increases differentiation of keratinocytes, leading to clearing of acanthosis nigricans (Bohm, 1999).

Melanoma

This is the second most common vulvar malignancy and accounts for up to 10 percent of all vulvar cancers. However, melanomas that develop in the vulva comprise only 1 to 2 percent of all melanoma cancer cases. Presenting symptoms include burning, pain, pruritus, a bleeding mass, local discoloration or ulcerations, and even dysuria (Trimble, 1992). Diagnosis and treatment of these lesions is discussed in Chapter 31, Melanoma (Ragnarsson-Olding, 1999; Wechter, 2004; Weinstock, 1994).

Nevus

Acquired nevi commonly develop in adolescence in sun-exposed areas, although vulvar skin is not immune (Krengel, 2005). In contrast, congenital nevi may be found on any skin surface at any age. Pigmented nevi warrant close surveillance, as more than half of all melanomas arise from pre-existing nevi.

Nevi are classified into three primary groups: junctional, compound, and intradermal. Junctional nevi are less than 1 cm in

diameter, flat with minimal surface elevation, and derive from melanocytes within the epidermis. Their color is uniform and lesion margins are well demarcated. Junctional nevi are the ones most likely to become malignant. Compound nevi involve both the dermis and epidermis. Lesions possess regular margins and range in size from 4 to 10 mm. As these lesions age, they may progress into intradermal nevi, which lie completely within the dermis and can become papular or pedunculated.

Therapy for nevi is primarily conservative with close observation in asymptomatic individuals. As lesions become palpable with subsequent irritation and bleeding, surgical excision serves both a diagnostic and therapeutic role.

DEPIGMENTATION

Vitiligo

The loss of epidermal melanocytes in areas of depigmented skin is termed *vitiligo* (Fig. 4-7). Global prevalence of this disease varies from 0.1 to 0.2 percent, with the incidence peaking in the second decade. No racial, ethnic, or socioeconomic populations harbor a greater propensity towards this disease, although the disease is more disfiguring in members of darker-skinned ethnic groups (Grimes, 2005).

FIGURE 4-7

Vulvar vitiligo. *(Courtesy of Dr. William Griffith.)*

Genetic factors have emerged as the most common cause of vitiligo (Zhang, 2005). Although its complex inheritance pattern is not fully understood, approximately 20 percent of patients have at least one affected first-degree relative. Vitiligo may also share pathogenesis with other autoimmune disorders, such as Hashimoto thyroiditis, Graves disease, diabetes mellitus, rheumatoid arthritis, and even psoriasis (Boissy, 1997).

Most commonly, depigmentation is generalized and symmetric, although distribution may also be acral, acrofacial, localized, and segmental. Lesions progress slowly over years.

Recently, there have been a number of advances in the treatment of vitiligo, including narrow-band UV-B phototherapy, targeted light therapy, and topical immunomodulators (Grimes, 2005; Yones, 2007).

Dermatologic Manifestations of Systemic Disease

CROHN DISEASE

Transmural granulomatous inflammation affecting the submucosa anywhere along the gastrointestinal tract is characteristic of Crohn disease. Four types of cutaneous involvement are associated with Crohn disease and include: (1) direct extension from the involved bowel; (2) extraintestinal involvement of the vulva, penis, abdominal wall, extremities, and submammary area; (3) pyoderma gangrenosum, erythema nodosum, and erythema multiforme; and (4) nutritional deficiency-related skin lesions (Burgdorf, 1981; Kim, 1992). Seen in nearly a quarter of women with Crohn disease, the classic perineal and vulvar deep, slit-like, "knife cut" ulcers seen in the inguinal, genitocrural, and interlabial folds typify extraintestinal involvement (Donaldson, 1978). Such lesions may predate gastrointestinal symptoms (Patton, 1990).

Therapy that is used to treat gastrointestinal manifestations of Crohn disease should also benefit metastatic Crohn lesions. Extensive genital surgery can be avoided with appropriate vulvar hygiene, proper nutrition, and close collaboration with a gastroenterologist familiar with the latest therapies for Crohn disease. In the event that surgical management is required, excision of the fistulous tracts is attempted, while reserving a total vulvectomy for extensive disease.

Solid Vulvar Tumors

Most solid vulvar tumors are benign and arise from local tissue. Less commonly, malignant lesions arise on the vulva and are typically of squamous cell epithelial origin. Rarely, solid vulvar tumors may develop as metastatic lesions (Fig. 4-8). Accordingly, many growths warrant biopsy if their nature is not obviously determined by visual inspection.

EPIDERMAL

Acrochordon

Commonly known as a skin tag, acrochordons are benign polypoid fibroepithelial lesions. These lesions are most often seen on the sides of the neck, axilla, or groin, and range from 1 to 6 mm in diameter. Of note, recent reports have found a relationship between acrochordons and diabetes mellitus (Demir, 2002). Insulin-mediated fibroblast proliferation may explain this relationship.

Clinically, an acrochordon is a soft sessile or pedunculated mass that is usually skin-colored and devoid of hair. Swelling or ulceration may be noted following chronic irritation or trauma. Surgical removal is recommended in cases of chronic irritation or for cosmetic reasons. Such lesions are easily removed under local anesthesia in an office setting.

Seborrheic Keratosis

Occasionally, vulvar manifestations of seborrheic keratosis may be observed in women with seborrheic keratosis on the neck, face, or trunk. Typically, seborrheic keratoses are slightly raised, sharply circumscribed verrucous lesions with a dark greasy appearance. The malignant potential of these slow-growing lesions is minimal. Therefore excision is offered only in cases of discomfort or disfigurement.

Keratoacanthoma

Keratoacanthomas are rapidly growing low-grade malignancies originating in pilosebaceous glands. Lesions begin as firm, round papules that progress to dome-shaped nodules with central craters. Untreated, the lesions will spontaneously regress within 4 to 6 months, leaving only a slightly depressed scar. Given its slight malignant potential and its resemblance to squamous cell carcinoma, surgical excision with 3- to 5-mm margins is recommended.

LEIOMYOMA

Vulvar leiomyomas are extremely rare tumors felt to arise from either smooth muscle within the vulva's erectile tissue or transmigration through the round ligament. Surgical excision to exclude leiomyosarcoma is warranted (Nielsen, 1996).

FIBROMA

Fibroma is a rare benign tumor of the vulva with a reported incidence of 0.03 percent (Chen, 2004). Fibromas arise from deep connective tissues by proliferation of fibroblasts. Lesions are primarily found on the labium majus, and range in size from 0.6 to 8 cm in diameter. Larger lesions often become pedunculated with a long stalk and may cause pain or dyspareunia. Surgical excision is the primary treatment for symptomatic lesions.

LIPOMA

A large, soft sessile or pedunculated mass composed of mature adipose cells is termed *lipoma* . Similarly to fibromas, observation is reasonable in the absence of patient complaints, whereas symptoms may prompt surgical excision. These lesions lack a fibrous connective tissue capsule and complete dissection may be complicated by bleeding requiring a larger incision. Accordingly, surgical excision in an outpatient surgical unit with appropriate anesthesia and instruments is prudent.

Cystic Vulvar Tumors

BARTHOLIN GLAND DUCT CYST AND ABSCESS

Mucus produced to moisten the vulva originates in part from the Bartholin glands. Obstruction of this gland's duct can lead to cystic enlargement that accounts for nearly 2 percent of all new gynecologic visits (Fig. 4-9). Cysts may become infected, and the purulent contents result in abscess development.

FIGURE 4-9

PATHOPHYSIOLOGY

Infection

Bartholin duct cysts form in direct response to obstruction of ductal outflow. Despite this understanding, the primary reason for cyst formation remains unknown. Abscess formation tends to develop in populations with demographic profiles similar to those at high risk for sexually transmitted infections (Aghajanian, 1994). Historically, women with bilateral Bartholin gland duct cysts were assumed to have been infected with *Neisseria gonorrhoeae* . However, resent studies have demonstrated a wider spectrum of organisms responsible for these cysts and abscesses. For example, Tanaka and colleagues (2005) examined 224 patients and approximately two bacterial species per case were isolated. A majority were caused by aerobic bacteria, of which *Escherichia coli* was the most common isolate. Interestingly, only five cases involved *N gonorrhoeae* or *Chlamydia trachomatis* (Tanaka, 2005).

Other theories for ductal obstruction include a change in mucus consistency, mechanical trauma from poorly repaired episiotomies, or even congenitally narrowed ducts. Since mucus retention leads to cyst distention, the size and speed of growth are influenced by sexual stimulation. Hence, rapid accumulation is observed during times of heightened sexual excitement.

Malignancy

After menopause, Bartholin gland duct cysts and abscesses are uncommon and should raise suspicion of neoplasia. Carcinoma of the Bartholin gland is rare, and its incidence approximates 0.1 per 100,000 women (Visco, 1996). A majority of lesions are squamous carcinomas or adenocarcinomas (Copeland, 1986).

Given the rarity of these cancers, Bartholin gland excision is typically not indicated. Alternatively, in women older than 40 years, drainage of the cyst and biopsy of suspicious cyst wall sites adequately excludes malignancy (Visco, 1996).

Symptoms

Most Bartholin gland cysts are small and asymptomatic except for minor discomfort during sexual arousal. When a lesion becomes larger or infected, women may experience severe vulvar pain the precludes them from walking, sitting, or engaging in sexual activity.

Diagnosis

A Bartholin gland enlargement can mimic several other vulvovaginal masses. Most cysts are unilateral, round or ovoid, and tense. Abscesses typically display surrounding erythema and are tender to palpation. The mass is usually located in the posterior labia majora or lower vestibule. Whereas most cysts and abscesses lead to asymmetry of labial anatomy, some smaller cysts may only be detected by palpation. Bartholin abscesses on the verge of spontaneous decompression will exhibit an area of softening where rupture will most likely occur.

Treatment

Small, asymptomatic cysts require no intervention except to exclude neoplasia in women older than 40 years. Multiple techniques exist for managing cysts that cause significant pressure symptoms or become infected. These include incision and drainage, marsupialization, and Bartholin gland excision, and are described and illustrated in Sections 41-6, Bartholin Gland Duct Incision and Drainage through 41-8, Bartholinectomy.

SKENE GLAND CYST AND ABSCESS

Ductal occlusion of the Skene gland, which is the largest paraurethral gland and located at the distal urethra, may lead to cystic enlargement and possible abscess formation (Chap. 26, Classification). Its etiology remains unknown, although many speculate that infection or trauma may predispose.

The main symptoms include urinary obstruction, dyspareunia, and pain. The primary treatment for these insignificant glandular enlargements is excision. In the presence of an acute abscess, a lesion should not be excised until infection subsides.

URETHRAL DIVERTICULUM

This is a cystic enlargement of a paraurethral gland. Typically found along the inferior urethral wall, these sacs communicate directly with the urethra and bulge into the anterior vaginal wall (see Fig. 26-3) (Lee, 2005). Although postvoid dribbling is a classic complaint, women may also note pain, dyspareunia, or urinary symptoms. On physical examination, a urethral diverticulum may be palpated as a slight bogginess along the length of the urethra. Urine or purulent drainage can be expressed with compression. Urethral diverticula are discussed further in Chapter 26, Urethral Diverticulum and their surgical management illustrated in Section 42-9, Urethral Diverticulum Repair.

VULVAR EPIDERMAL INCLUSION CYST

These are common vulvar cysts, often termed sebaceous cysts, which result from folding of the squamous vulvar epithelium beneath the epidermis. They are firm, mobile, nodular lesions, and are filled with white or yellow caseous material.

In general, inclusion cysts are asymptomatic and require no therapy. Symptomatic, noninfected lesions, may be removed by wide excision of the entire cyst or by punch biopsy of the lesion with extrusion of cyst contents and cyst wall through the biopsy opening (Moore, 2007). Lee and colleagues (2006) found similarly low recurrence rates and superior healing with the punch technique in a randomized prospective study of 60 patients.

Vulvodynia

In October 2003, the 17th ISSVD World Congress unanimously agreed upon defining vulvodynia as "vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder" (Table 4-8) (Moyal-Barracco, 2004). The pain of vulvodynia is described as spontaneous (unprovoked) or triggered by physical pressure (provoked) such as sexual contact, tampon insertion, or fingertip pressure. In addition, the term *vestibulitis* was eliminated from ISSVD terminology since inflammatory changes have not been consistently documented.

INCIDENCE

Unfortunately, limited information is available regarding the number of women with vulvodynia. This can be explained in part by an average delay of 4 years before reaching the appropriate diagnosis, and by patient underreporting secondary to psychosexual embarrassment (Graziottin, 2004). In a population study by Harlow and Stewart (2003), 55 percent of women with chronic vulvar pain sought treatment. Of those that did, more than 60 percent saw three or more doctors, many of whom were unable to provide an accurate diagnosis. Hispanic women are 80 percent more likely to experience chronic vulvar pain compared with African-American and Caucasian women. There is a wide age variation in prevalence patterns.

ETIOLOGY OF VULVODYNIA

The precise etiology of vulvodynia is unknown. Although many factors have been investigated, most agree that the process is multifactorial and requires an interdisciplinary approach to treatment (Babula, 2004; Bouchard, 2002; Danielsson, 2001).

NEUROPATHIC CHANGES

Serotonin-containing neuroendocrine cells are found at multiple sites in the female genital tract. Substance P axons have been demonstrated in the ducts of vestibular glands in close proximity to these cells. This is an important association for two reasons. First, neurogenic inflammation through increased vascular permeability and vasodilatation are felt to be mediated by substance P and serotonin. Evidence of increased blood flow to the most painful area on the vestibular mucosa has been documented using laser Doppler perfusion imaging (Bohm-Starke, 2001). Second, this association may explain the pinpoint tenderness of vestibular glands in those with vulvodynia in the absence of other physical findings (Warner, 1996).

DIAGNOSIS

An evidence-based algorithm for the diagnosis of vulvodynia is provided in Fig. 4-10 (Haefner, 2005). Given that vulvodynia is a diagnosis of exclusion, an extensive history is critical to securing the correct diagnosis.

Symptoms of Vulvodynia

Vulvodynia refers to vulvar discomfort of at least 3 to 6 months' duration without an identifiable cause (Table 4-9). The location and temporal pattern of dyspareunia can help predict the physical diagnosis (Meana, 1997). Many women with localized vulvodynia may describe burning, itching, or cutting pain within affected areas (Bergeron, 2001). Pain may follow a touch stimulus (allodynia) such as wearing tight clothing or undergarments or undergoing pelvic examination. Sensations are intermittent and even episodic with exacerbations noted premenstrually (Arnold, 2006).

Table 4-9 Questions Appropriate for Investigation of Vulvodynia

1. *When* did the pain begin? Was it sudden? Was there a sentinel event?
2. *How* did the pain begin? Was it gradual? Acute? Spontaneous?
3. *Describe* the pain? Is it Localized? General? Provoked? Unprovoked? How intense is it?
4. *Aggravating* factors? Position? Touch?
5. *Relieving* factors? Prior therapy?
6. *Associated* symptoms? Urinary? Skin complaints? Itching?
7. *Impact* of the pain?

This can help provide clear goals for treatment and serve as a point of reference to assess therapy.

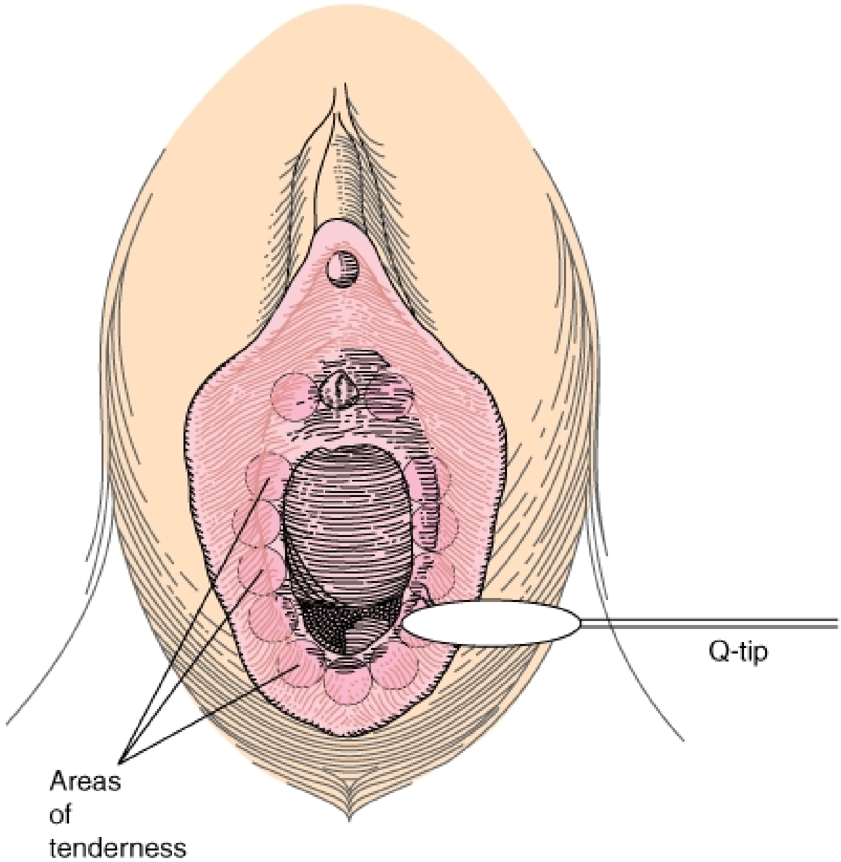
Questioning should seek to identify frequently associated comorbid conditions or other risk factors, such as irritable bowel syndrome, interstitial cystitis, psychological disorders, relationship discord, or prior infectious disease such as herpes simplex or zoster (Arnold, 2007). Documentation of past surgical procedures may help identify injury to the pudendal nerve. A sexual history may reveal clues of past or current abuse, unfavorable coital patterns, and contraceptive preferences that could provoke vulvodynia. Additionally, clinicians should inquire about recurrent candidiasis; prior genital trauma, including childbirth-related injuries; and current hygienic practices, including the use of feminine products, panty liners, soaps, undergarment fabrics, and perfumes. Importantly, prior therapies should be documented to avoid unnecessary treatment repetition.

Physical Examination

By definition, vulvodynia lacks identifying physical markers. Therefore a thorough examination is first required to exclude other possible pathologies. Inspection of the external vulva is followed by examination of the vestibule tissue to search for foci of erythema. Colposcopic investigation of the vulva and directed biopsies will exclude other pathology (see Chap. 29, Colposcopy).

Systematic pain mapping of the vestibule, perineum, and inner thigh is completed and serves as a reference to assess treatment success (Fig. 4-11). A cotton swab is used to check for allodynia and hyperesthesia. The end can first be unwound to form a cotton-fiber wisp. Subsequently, the wooden stick is broken to form a sharp point to retest the same areas. The severity of pain on a five- or ten-point scale should be recorded and followed over time.

FIGURE 4-11



Pain can be assessed and mapped by systematically touching a cotton-tipped applicator to the vulva. *(From Howard, 2000, with permission.)*

Laboratory Testing

Although no specific laboratory test can diagnose vulvodynia, a wet prep of vaginal secretions, vaginal pH evaluation, yeast subtyping, and bacterial markers are helpful in excluding underlying vaginitis (see Table 3-15). Ulcerative lesions should prompt biopsy consideration and cultures for herpes simplex virus. Herpes viral serology may prove helpful but patient counseling regarding the interpretation of results is recommended.

TREATMENT

In the absence of well-designed clinical trials, no specific therapy for vulvodynia is deemed superior. In general, a combination of multiple medical forms of therapy may be required to stabilize and improve patient symptoms. In the absence of improvement with medical treatment, surgical excision is a final option.

MEDICAL THERAPY

Vulvar Care

The first step in managing all vulvar disorders includes gentle vulvar care. As shown in Table 4-2, cotton undergarments, avoidance of vulvar irritants, restoration of the barrier function, and appropriate lubrication during intercourse are the mainstays of vulvar care (Haefner, 2005).

Biofeedback and Physical Therapy

If components of back pain, muscle spasm, or vaginismus are present, a trained vulvar physical therapist can improve symptoms and coital frequency through use of internal and external massage, myofascial release techniques, acupressure, and pelvic floor retraining (Bergeron, 2002).

Behavioral Therapy

Many believe vulvodynia is more than a psychosexual problem. Compared with the general population, no differences in marital contentment or psychological distress are found (Bornstein, 1999). Nevertheless, early counseling should include a basic assessment of sexual function and offer education regarding foreplay, sexual positions, lubrication, and alternatives to vaginal intercourse.

Topical Medications

A generous amount of 5-percent lidocaine ointment applied to the vestibule 30 minutes prior to sexual intercourse has been shown to significantly decrease dyspareunia (Zolnoun, 2003). Long-term use may lead to healing by minimizing feedback pain amplification (see Chap. 11, Neuropathic Pain). Numerous other topical anesthetic preparations have been used and reported to have variable success. Particular caution, however, should be exercised with benzocaine, which has been associated with increased rates of contact dermatitis.

Eva and colleagues (2003) found decreased estrogen receptor expression in women with vulvodynia. However, topical or intravaginal estrogen therapy has yielded mixed results.

Oral Medications

The two major classes of oral medications found to help in the treatment of vulvodynia are antidepressants and anticonvulsants.

Tricyclic antidepressants (TCAs) have become first-line agents in the treatment of vulvodynia. Reported response rates to TCAs may reach 47 percent (Munday, 2001). In our experience, amitriptyline started between 5 and 25 mg orally nightly and increased as needed by 10 to 25 mg weekly, yields the best results (see Table 11-5). Final daily doses should not exceed 150 to 200 mg. Importantly, women should remain compliant despite the nearly 4-week lag required to achieve significant pain relief.

Cases resistant to TCAs may be treated with the anticonvulsants, gabapentin, or carbamazepine (see Table 11-5) (Ben David, 1999). Gabapentin is initiated at a dosage of 100 mg orally three times daily and gradually increased within 6 to 8 weeks to a maximum daily dose of 3600 mg. Once this dose is reached, pain may be reassessed after 1 to 2 weeks (Haefner, 2005).

Intralesional Injections

In cases of localized vulvodynia, trigger point injections using a combination of steroids and anesthetics, such as a mixture of a 4:1 ratio of methylprednisolone acetate and lidocaine cloridrate, can be injected directly into the lesion (Murina, 2001).

Surgical Therapy

Women with vulvodynia who fail to improve clinically despite aggressive medical therapy are candidates for surgical intervention. Options include local excision of a precise pain locus; complete resection of the vestibule, termed *vestibulectomy* ; or resection of the vestibule and perineum, known as *perineoplasty* . These are illustrated in Section 41-9, Vestibulectomy. Traas and colleagues (2006) reported high success rates with vestibulectomy among women less than 30 years of age. Perineoplasty is the most extensive of the three procedures, and the incision extends from just below the urethra to the perineal body, usually terminating above the anal orifice. This procedure may be selected if significant perineal scarring is suspected to contribute to dyspareunia.

Congenital Lesions

Structural congenital abnormalities of the lower reproductive tract are uncommon and include those resulting from organ atresia, failure of tissues to regress or to fuse normally, and abnormal hormone signaling. These are discussed in detail in Chapter 18.

Infectious Lesions

Infection is a common cause of benign vulvar disease and may involve bacteria, fungi, viruses, or parasites. Ulcerative, proliferative, or suppurative lesions may result, and each is discussed in Chapter 3.

Preinvasive and Malignant Disease

Cancerous and preinvasive neoplasias of the vulva are uncommon and typically are found as unifocal lesions in older women. However, significant rises in human papillomavirus-related multifocal vulvar intraepithelial neoplasia (VIN) have recently been noted in younger women. Symptoms are variable and may include severe pruritus, pain, and dyspareunia. Because a well-defined mass is not always present, vulvar areas with thickened epithelium or persistent areas of ulceration, pain, or pruritus should prompt biopsy. Most neoplastic lesions are of squamous cell origin and carry a favorable prognosis if identified and treated early (see Chaps. 29, Vulvar Preinvasive Lesions and 31, Lymph Node Metastasis).

Vulvovaginal Trauma

BLUNT TRAUMA

Given the anatomic location and adipose padding of the labia majora, accidental vulvar and vaginal injuries are rare. Conversely, as children lack such well-developed fat pads in the labial area, objects such as bicycle bars, gymnastics beams, and bench rails may increase their risk of straddle injuries (Virgili, 2000). The usual sequela of blunt trauma to the vascularly-rich vulva is a hematoma.

Often requiring a general anesthetic, a thorough examination of the vulva and vagina will allow estimation of the stability and size of the hematoma, and the integrity of the surrounding organs such as the bowel, bladder, urethra, and rectum. Fortunately, if no associated organ injury is noted, the venous nature of vulvar hematomas make them candidates for conservative management with cool pack, Foley drainage of the bladder, and adequate pain control (Propst, 1998).

Vaginal hematomas larger than 4 cm should be explored surgically in search of bleeding vessels to secure. An unstable patient may result from retroperitoneal bleeding from a retracted vessel (Gianini, 1991). Postoperatively, a vaginal pack may help tamponade any venous leakage.

LACERATION

Penetrating trauma accounts for most vaginal injuries. Common causes of trauma include pelvic fracture, forced inanimate objects, coitus, and hydraulic forces such as those experienced with water skiing (Smith, 1996).

Examination under anesthesia is often necessary to perform a thorough assessment and to exclude intraperitoneal damage. Treatment goals include achieving hemostasis and restoration of normal anatomy. Irrigation, dÃ©bridement, and primary repair are desirable. On occasion, infection may require allowing a laceration to close by secondary intent. Ultimately, techniques for repairing vulvovaginal trauma are similar to those used for obstetric lacerations.

If the peritoneal cavity has been breached, a transabdominal exploration by either laparotomy or laparoscopy is mandatory to exclude inadvertent visceral injury.

SEXUAL INJURY

Differentiating straddle injury and sexual abuse is often challenging, as injury patterns do not accurately confirm or exclude sexual trauma. Diagnosis requires careful inquiry and correlation of described mechanisms of injury with physical examination findings.

Certain characteristics may serve as red flags for sexual abuse. In an infant or child, these include extensive trauma and injury at an extragenital site, genital secretions, lack of correlation between history and physical examination, or condyloma acuminata (Dowd, 1994; Emans, 1987). Moreover, injuries to the posterior fourchette; those of the hymen that extend from 3 to 9 o'clock; or vaginal, rectal, or peritoneal perforation should increase suspicion for sexual abuse (Bond, 1995).

In contrast, a unilateral, single, or stellate laceration or bruise in the same shape as that of the described blunt object supports a diagnosis of unintentional injury. In addition, nonpenetrating straddle injuries are more common in unintentional settings. Thus, lacerations or abrasions of the labia minora, mons pubis, and clitoris that are anterior or lateral to the hymen are typical of straddle injury.

VAGINAL LESIONS

Foreign Bodies

Vulvovaginal injuries may result from trauma caused by a foreign body placed into the vagina. Although seen in women of all ages, the nature of the object varies with the affected population. For example, small objects may lodge in a child's vagina during play or self-exploration or an adolescent may complain of being unable to retrieve a forgotten tampon or broken condom. Sexual misadventure or abuse can usually explain the etiology of objects found in adult women. Two items in particular warrant further discussion: the forgotten tampon and vaginal pessary.

Women with a forgotten tampon will typically complain of a foul-smelling vaginal discharge with some associated pruritus, discomfort, or dysfunctional bleeding. After further discussion, a history of multiple unsuccessful retrieval attempts may be revealed. In the absence of a leukocytosis, fever, or evidence of an endometritis or salpingitis, simple removal of the tampon is appropriate. Vaginal lavage to clean the vagina is not indicated, as it may actually increase the risk of ascending infection.

Vaginal pessaries are commonly used for the conservative treatment of pelvic organ prolapse (see Chap. 24, Types of Pessaries). Atrophic vaginal epithelium increases the risk of ulcerative or erosive complications with inappropriately sized devices. Intravaginal estrogen cream and close physician assessments with periodic removal are essential in avoiding such injuries. Complaints of bloody or foul-smelling discharge should warrant an immediate inspection of the vaginal vault.

Epidermal Inclusion Cysts

A collection of desquamated epithelial cells encapsulated by a wall of stratified squamous epithelium in the dermis of the vagina is known as an epidermal inclusion cyst. Inclusion cysts are variable in size and are visible through the vaginal mucosa as round white masses. Generally, the cyst is filled with viscous, gritty, or caseous foul-smelling contents that closely resemble a purulent exudate. As with those found in the vulva, epidermal inclusion cysts are generally asymptomatic and require no further evaluation except in the case of infection, in which incision and drainage are recommended.

Diethylstilbestrol-Induced Reproductive Tract Abnormalities

In the mid-1900s, diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed for a number of pregnancy problems to women in the United States (see Chap. 18, Acquired Uterine Defects). These women's daughters, who were exposed in utero to DES, showed increased rates of vaginal clear cell adenocarcinoma and congenital reproductive tract changes (Herbst, 1971). These changes included transverse vaginal septums, circumferential ridges involving the vagina and cervix, and cervical collars (see Fig. 32-7). Additionally, areas of columnar epithelium within the vaginal squamous mucosa may be found in these women, and is termed *vaginal adenosis* . Vaginal adenosis typically appears red, punctuate, and granular. Common symptoms and signs include vaginal irritation, discharge, and metrorrhagia, in particular postcoital bleeding.

Gartner Duct Cyst

These uncommon vaginal cysts develop from remnants of the mesonephric (Wolffian) ducts (see Fig. 18-2). They are typically asymptomatic and are usually found within the lateral vaginal wall during routine examination. Symptoms, however, may include dyspareunia, vaginal pain, and obstruction to insertion of tampons or other vaginal devices. Examination reveals a tense cyst that is palpable or seen to bulge beneath the vaginal wall. Observation alone is reasonable in most cases, although marsupialization or excision may be appropriate for symptomatic Gartner duct cysts.

CERVICAL LESIONS

Eversion

The squamocolumnar junction (SCJ) is the border between the columnar epithelium of the endocervix and the squamous epithelium of the ectocervix. Endocervical tissue in some women may move out from the endocervical canal in a process termed eversion (see Fig. 29-2). As a result, the SCJ lies further from the external cervical os. To perform an adequate Pap smear, the clinician must identify the circumferential path of the SCJ prior to sampling.

Nabothian Cyst

Mucus-secreting columnar cells line the endocervical canal. During squamous metaplasia, squamous epithelium may cover nests of glandular cells, predisposing them to accumulation of secretions. As this benign process continues, smooth, clear or yellow glandular elevations are visible during routine examination (Fig. 4-12). Nabothian cysts warrant no further therapy.

Endocervical Polyp

One of the most common benign neoplasms of the cervix is a hyperplastic projection of the endocervical folds known as an *endocervical polyp* (Fig. 4-13). Lesions are easily found during routine cervical surveillance and may be associated with leukorrhea or postcoital spotting. In the presence of a slender stalk, polyp removal may be accomplished by a continuous twisting of the lesion with ring forceps. Twisting leads to occlusion of supporting vessels and avulsion of the mass. A thick-pedicled polyp is best treated by surgical excision. Excised cervical polyps require pathologic evaluation to exclude malignancy.

CONTRACEPTION AND STERILIZATION: INTRODUCTION

A wide variety of effective methods of regulating fertility is currently available. None is completely without side effects or categorically without dangerâ€"for example, latex condoms can cause anaphylactic reactions. That said, and as shown in Table 5-1, contraception poses less risk than does pregnancy. In fact, for most women it is safer to use contraception than it is to drive a car (Hatcher, 2004).

CONTRACEPTION

Pregnancy rates at 1 year approach 90 percent for sexually active fertile women who do not use contraception. Because ovulation often precedes menstruation, young women should be advised to use contraception whenever they begin sexual activity. Providing contraceptive advice for the woman nearing menopause is harder, because it is difficult to predict when fertility has ended.

Contraceptive Methods

Methods of variable effectiveness currently employed in the United States include:

- Oral steroidal contraceptives
- Injected steroidal contraceptives
- Intrauterine devices

- Transdermal and transvaginal steroidal contraceptives
- Physical, chemical, or barrier techniques
- Sexual abstinence around the time of ovulation
- Breast feeding
- Permanent sterilization

The most recent nationally representative data concerning contraceptive use were collected in 1995 (Fig. 5-1). Additionally, in 2002, Bensyl and associates (2005) reported results from the Behavior Risk Factor Surveillance System (BRFSS). Although results varied, sometimes substantially, across states as well as by gender and ethnic group, the methods generally reported were similar to those shown in Table 5-1.

Contraceptive use in the United States circa 1995 for users aged 15 to 44 years. FAB = fertility awareness-based method; IUD = intrauterine device.

Based on the results of the 1995 National Survey of Family Growth, approximately one thirdâ€"2.65 millionâ€"of all pregnancies were unintended. Indeed, half of unintended pregnancies were in women using a method of contraception at the time of conception (Henshaw, 1998). Estimates of the failure rate during the first year of use are given in Table 5-2.

Obviously, the importance of accurate, timely, and complete counseling and education regarding correct product use is essential to the contraceptive efficacy of any method. The large number of unintended pregnancies in women using contraception is evidence of deficits in contraception dispensing, prescribing, and education. Because of this, many women have misperceptions about the risks of contraception use, as well as how to effectively implement them (Picardo, 2003). According to Dailard (2005), if comprehensive sex education was provided, a 40-percent decrease in unintended pregnancies could be achieved.

HORMONAL CONTRACEPTIVES

These types of contraceptives are currently available in a wide variety of forms: pill, injection, transdermal patch, implant, and a transvaginal ring. Combination oral contraceptivesâ€”"The Pill"â€”consist of a combination of estrogen and progestin, or a progestin only pillâ€”the *mini-pill.* Other forms contain progestins alone or a combination of estrogen and progestin. Unfortunately, no reliable reversible male hormonal contraceptives have been developed (Kamischke, 2004).

Estrogen Plus Progestin Contraceptives

Combination oral contraceptives (COCs) are the most frequently used method of hormonal contraception, and an almost bewildering variety are marketed (Table 5-3). Although generic formulations accounted for only 3.6 percent of prescriptions in 1990, they accounted for 18 percent by 2001 (Keith, 2001).

These oral contraceptives typically consist of a combination of an estrogen and a progestational agent taken daily for 3 weeks and then stopped for 1 week, during which time there is withdrawal uterine bleeding. Longer durations of active hormone administration, designed to minimize withdrawal bleeding, have been investigated (Edelman, 2006; Miller, 2003). Such extended-cycle products are now available: Seasonale and Seasonique (Barr Pharmaceuticals, Pomona, NY).

MECHANISMS OF ACTION

The contraceptive actions of COCs are multiple. The most important effect is to prevent ovulation by suppression of hypothalamic gonadotropin-releasing factors, which in turn prevents pituitary secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Estrogen suppresses FSH release and stabilizes the endometrium to prevent metrorrhagia, which is often called *breakthrough bleeding* in this setting. Progestins inhibit ovulation by suppressing LH, they thicken cervical mucus to retard sperm passage, and they render the endometrium unfavorable for implantation.

The net effect is extremely effective ovulation suppression, inhibition of sperm migration, and creation of an unfavorable endometrium for implantation. Thus, combined oral contraceptives, *if taken daily for 3 out of every 4 weeks,* provide virtually absolute protection against conception.

PHARMACOLOGY

In the United States, the only estrogens available are *ethinyl estradiol,* and less commonly its 3-methyl ether, *mestranol* . Almost all currently available *progestins* are 19-nortestosterone derivatives, but one is an aldosterone derivative. Although individual progestins were initially chosen because of their progestational potency, they are often compared and prescribed based on their presumed estrogenic, antiestrogenic, and especially their androgenic effects. Despite this, a scientific basis for such selective prescribing is lacking (Wallach, 2000). For example, all progestins lower serum free testosterone levels and inhibit 5α-reductase

and thus conversion of testosterone to the active dihydrotestosterone. Because of this, all progestins are expected to have salutary effects on androgen-related conditions such as acne (see Chap. 17, Acne).

DOSAGE

Since their initial development, COCs now contain markedly reduced amounts of estrogen and progestin. As a result, because most adverse effects are dose related, side effects have similarly decreased with modern pill dosages. For most, the lowest acceptable dose is governed by the ability to prevent unacceptable breakthrough bleeding. Although daily estrogen content varies from 20 to 50 μg of ethinyl estradiol, most pills contain 35 μg or less (see Table 5-3). The amount of progestin can be varied in two ways: (1) progestin dose remains constant during the cycleâ€”*monophasic* pills, and (2) progestinâ€”and in some, estrogenâ€”dosage varies during the cycleâ€”*biphasic* and *triphasic* pills.

Ideally, women should start COCs on the first day of a menstrual cycle, in which case an additional contraceptive method is unnecessary. A more traditional scheduleâ€”the *Sunday start* â€”requires pill initiation on the first Sunday following menstruation onset. This schedule necessitates use of an additional method for 1 week to ensure that conception does not occur. Alternatively, immediate initiation of COCs, regardless of menses, has been shown to be safe and to improve short-term continuation rates (Westhoff, 2007).

To obtain maximum protection and promote regular use, most suppliers offer dispensers that provide 21 sequential color-coded tablets containing hormones, followed by seven inert tablets of another color. It is important for maximum contraceptive efficacy that each woman adopt an effective scheme for assuring dailyâ€”or nightlyâ€—self-administration.

If one dose is missed, conception is unlikely with higher-dose monophasic estrogen and progestin pills. When this is recognized, a woman may choose to double that day's dose to minimize breakthrough bleeding. The remainder of the pill pack is completed with one pill taken daily.

If several doses are missed or lower-dose pills are used, the next dose is doubled and an effective barrier technique is added for the subsequent 7 days. The remainder of the pill pack is completed with one pill taken daily. Alternatively, a new pack can be started with a barrier method as additional contraception for a week. If withdrawal bleeding does not follow during the week of placebo pills, a woman should continue the pills but seek medical attention to exclude pregnancy.

PHASIC PILLS

These preparations were developed in an effort to reduce the amount of total progestin per cycle without sacrificing contraceptive efficacy or cycle control. The reduction is achieved by beginning with a low dose of progestin, and increasing it later in the contraceptive cycle. Theoretically, the lower total dose should result in a reduction in progestin-attributable metabolic changes and adverse side effects. The estrogen dose may be kept constant, or it also may be increased later in the cycle. In all such preparations, however, estrogens are kept between 20 and 40 μg of ethinyl estradiol (see Table 5-3).

Despite the cited advantages, both theoretical and actual, there are distinct disadvantages to triphasic formulations. These include confusion due to multicolored pills and breakthrough bleeding or spotting, which likely is increased compared with monophasic pills (Woods, 1992).

DRUG INTERACTIONS

Oral contraceptives interfere with the actions of some drugs (Table 5-4). Conversely, some drugs decrease the contraceptive effectiveness of COCs (Table 5-5). Phenytoin and rifampin are believed to increase breakthrough bleeding and reduce contraceptive effectiveness of pills containing less than 50 μg of ethinyl estradiol (Hatcher, 1998). Many antiretrovirals decrease contraceptive efficacy, therefore barrier contraceptive methods are recommended (University of California at San Francisco, 2005). Although package inserts for some broad-spectrum antibiotics such as ampicillin and tetracycline warn that they may reduce the efficacy of oral contraceptives, this likely is not true. Any decreased efficacy is related to underlying associated gastrointestinal symptoms, such as vomiting or diarrhea, which can decrease absorption. Another agent, vitamin C, competes for active sulfate in the intestinal wall and increases the bioavailability of ethinyl estradiol. Thus, erratic use of vitamin C can result in breakthrough bleeding (Kubba, 1993).

SAFETY

In general, oral contraceptives have proven to be safe for most women. The possibility of adverse effects from COCs has received so much attention for so long that clinicians as well as the public are frequently confused by the often conflicting reports.

BENEFICIAL EFFECTS

As shown in Table 5-6, there are many beneficial effects from use of the combined estrogen plus progestin contraceptives.

Table 5-6 Some Benefits of Combination Estrogen Plus Progestin Oral Contraceptives
Increased bone density
Reduced menstrual blood loss and anemia
Decreased risk of ectopic pregnancy
Improved dysmenorrhea from endometriosis
Fewer premenstrual complaints
Decreased risk of endometrial and ovarian cancer
Reduction in various benign breast diseases
Inhibition of hirsutism progression
Improvement of acne
Prevention of atherogenesis
Decreased incidence and severity of acute salpingitis
Decreased activity of rheumatoid arthritis

POSSIBLE ADVERSE EFFECTS

A number of metabolic changes, often qualitatively similar to those of pregnancy, have been identified in women taking oral contraceptives. For example, total plasma thyroxine and thyroid-binding proteins are elevated. Plasma cortisol concentration increases with a nearly comparable increase in transcortin. It is extremely important, therefore, that these pregnancy-like effects be considered when evaluating laboratory tests.

Lipids and Lipoproteins

In general, COCs increase serum triglyceride and total cholesterol levels. Estrogen decreases concentration of low-density lipoprotein (LDL) cholesterol and increases high-density lipoprotein (HDL) cholesterol. Some progestins cause the reverse (Stadel, 1981). The clinical consequences of these perturbations have almost certainly been overstated, and their impact on lipids is inconsequential for the vast majority of women (Wallach, 2000).

Carbohydrate Metabolism

Concern over deterioration in glucose tolerance, mediated principally by the progestin, is no longer warranted with current formulations (Speroff, 2001). In healthy women, large prospective studies with long-term surveillance demonstrate that COCs do not increase the risk of diabetes (Rimm, 1992). In fact, they do not increase the risk that women with a history of gestational diabetes will progress to overt diabetes (Kjos, 1998). Combination oral contraceptives may be used in women who have diabetes not complicated by associated vascular disease.

Protein Metabolism

Estrogens increase hepatic production of a variety of globulins. Increased angiotensinogen production appears to be dose related, and its conversion by renin to angiotensin I has been suspected to be associated with so-called *pill-induced hypertension* (Hypertension). Fibrinogen, and likely factors II, VII, IX, X, XII, and XIII, are increased in direct proportion to estrogen dose (Comp, 1996; Kaunitz, 1999). The relationship of these increased clotting factors to venous and arterial thrombosis is discussed in Hypertension, but the incidences of both forms of thrombosis appear to be estrogen-dose related (Mann, 1982).

Liver Disease

Cholestasis and *cholestatic jaundice* are uncommon complications of oral contraceptives. If they develop, signs and symptoms clear when the COCs are stopped. It appears that oral contraceptives may accelerate the development of gallbladder disease in women who are susceptible, but there is no overall increased long-term risk (Royal College of General Practitioners, 1982; Strom, 1986). There is no reason to withhold oral contraceptives from women who have recovered from viral hepatitis.

Neoplasia

A stimulatory effect on some cancers is always a concern with female sex steroids. Despite this, a number of studies indicate that it is unlikely that hormonal contraception causes cancer (Cancer and Steroid Hormone Study, 1986, 1987a, 1987b; Prentice, 1987; Schlesselman, 1988). In fact, a protective effect against ovarian and endometrial cancer was shown. There are, however, conflicting reports concerning the risks of premalignant and malignant changes of the liver, cervix, and breast.

Liver Cancer

Older contraceptives with larger estrogen doses were linked circumstantially with *hepatic focal nodular hyperplasia* and benign *hepatic adenoma* . Since that time, large studies of women taking contemporary low-dose oral contraceptives do not support such an association (Hannaford, 1997; Heinemann, 1998). Additionally, although an association between prolonged oral contraceptive use with *hepatocellular carcinoma* was reported by Neuberger and associates (1986), the large multicenter World Health Organization Study (1989) refutes this.

Cervical Cancer

There is a correlation between the risk of *cervical dysplasia* and oral contraceptive use, and the risk of *cervical cancer* increases after 5 years (Thomas, 1996; Vessey, 1983; Zondervan, 1996). It is unclear if these associations have a causal basis. For example, COC users are not protected from exposure to human papillomavirus unless they also use a barrier method. They also are more frequently screened cytologically for cervical cancer, and thus more likely to be diagnosed with dysplasia (Butterworth, 1992).

Breast Cancer

It is unclear whether oral contraceptives contribute to the development of *breast cancer* . In the largest study, no increased risk for breast cancer among COC users was noted (Cancer and Steroid Hormone Study, 1986). Moreover, risk did not vary according to specific preparations or duration of use. In addition, the Collaborative Group on Hormonal Factors in Breast Cancer (1996) re-analyzed data from 54 studies that included more than 53,000 women with breast cancer compared with over 100,000 controls. They found a small and significantly increased relative risk of breast cancer in current users of COCs. For women who had stopped use, relative risk was 1.16 at 1 to 4 years after stopping, and 1.07 at 5 to 9 years after stopping. The risk was not influenced by age at first use, duration of use, family history of breast cancer, first use prior to pregnancy, or the dose or type of hormone used. The lack of correlation with these factors calls into question the causal nature of the association. In this study, tumors associated with COC use tended to be less aggressive and to be detected at an earlier stage, a finding consistent with the possibility that the increased risk of breast cancer diagnosis was due to greater surveillance among users. In a recent case-control studyâ€"4,575 cases and 4,682 controlsâ€"there was no relationship between either current or past COC use and breast cancer (Marchbanks, 2002).

Current data neither support nor refute an association between COCs and ovarian or breast cancer among women heterozygous for *BRCA1* and *BRCA2* genes. The risks of unplanned pregnancy need to be considered along with those of any method of contraception (Grenader, 2005; McGuire, 2004; Milne, 2005). As a corollary, COC use for ovarian cancer *prevention* in these women is not currently advised (Modan, 2001).

Nutrition

Changes in serum levels of several nutrients, similar to those induced by normal pregnancy, have been described for women who use oral contraceptives. Lower plasma levels are reported for ascorbic and folic acid, vitamin B_6 (pyridoxine) and vitamin B_{12} , niacin, riboflavin, and zinc. An adequate diet is sufficient prophylaxis against any detrimental deficiency (Mooij, 1991).

Cardiovascular Effects

There are a number of infrequent but significant cardiovascular risks associated with hormonal contraceptive use.

Thrombosis and Embolism

The risk of *deep vein thrombosis* and *pulmonary embolism* is increased in women who use oral contraceptives (Realini, 1985; Stadel, 1981). This risk appears increased with transdermal patch use compared with COC use (Cole, 2007). These risks clearly are estrogen-dose related, and are decreased with formulations containing 20 to 35 µg of ethinyl estradiol (Westhoff, 1998). In an evidence-based review of six studies, Mishell and associates (2000) estimated the risks of venous thromboembolism in COC users. They concluded that the risk is increased three- to fourfold in current usersâ€"but not former users. The general population risk is lowâ€"about 1 per 10,000 woman-yearsâ€"and thus the incidence with COCs of 3.0 to 4.0 per 10,000 woman years is still low. Importantly, the risk is clearly lower than the incidence of 5.7 per 10,000 woman years estimated for pregnancy.

The enhanced risk of thromboembolism appears to decrease rapidly once COCs are stopped. Women who develop thromboembolism while taking estrogen-containing contraceptives, however, also appear to be at increased risk during pregnancy and postpartum. Those most at risk for venous thrombosis and embolism include women with some of the thrombophiliasâ€"for example, protein C or S deficiencies or factor V Leiden mutation (Comp, 1996; Mohllajee, 2006, van Vlijmen, 2007). Other clinical factors that increase the risk of venous thrombosis and embolism are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle (Hatcher, 2004).

The little evidence of an increased risk of *perioperative thromboembolism* and oral contraceptives is based on older, high-estrogen preparations. There are no studies of low-dose formulations, and any decision to stop their use prior to surgery should be made individually.

Stroke

According to the World Health Organization Collaborative Study (1998), *ischemic* and *hemorrhagic strokes* are uncommon in nonsmoking women younger than 35 years. Their incidence is 10 and 24 events per 1 million woman years, respectively. The earlier reports by Lidegaard (1993, 1998) of an increased risk of stroke in women using low-dose estrogen contraceptives stimulated a number of focused studies. At least five subsequent studies concluded that COC use by healthy, nonsmoking women is not associated with an increased risk of stroke (Petitti, 1996; World Health Organization Collaborative Study, 1996). In two of these studies, women who took COCs were at a higher risk of stroke if they had hypertension, were smokers, or had migraine headaches (Mishell, 2000; Schwartz, 1998).

Women taking COCs who have *migraine headaches with aura* have a two- to fourfold increased risk of stroke compared with nonusers (Curtis, 2002). This finding led the World Health Organization (WHO) to change the Medical Eligibility Criteria to exclude women with migraines from taking COCs. It seems wise to also preclude women who have *migraine headaches without aura* from taking these combination contraceptives. A progestin-only pill, barrier methods, or an IUD is more appropriate (World Health Organization, 2004).

Hypertension

An association between COCs and *hypertension* was apparent by the late 1960s. Earlier higher-dose contraceptives, presumably in response to estrogen, increased plasma angiotensinogen in most women, although only a few became hypertensive. Current low-dose formulations increase the absolute risk of clinically significant hypertension only slightly (Chasan-Taber, 1996). The development of gestational hypertension, including preeclampsia, does not preclude subsequent COC use. That said, women who currently have hypertension need to be thoroughly evaluated (Curtis, 2002). The American College of Obstetricians and Gynecologists (2005b) recommend control of hypertension before COC use is considered.

Myocardial Infarction

Low-dose oral contraceptives are not associated with an increased risk of *myocardial infarction* in women who are nonsmokers (Mishell, 2000; Petitti, 1998; Sidney, 1996, 1998; World Health Organization Collaborative Study, 1997). In fact, the American College of Obstetricians and Gynecologists (2000b) states there is no contraindication to oral contraceptives in nonsmoking women older than 35 years. Also, the Food and Drug Administration (FDA) revised labeling of oral contraceptives to remove restrictions for nonsmoking women older than 40. It is important to recognize that smoking is an independent risk factor for myocardial infarction,

and that smoking and oral contraceptives act synergistically to increase this risk, especially beyond age 35.

Effects on Reproduction

Postpill amenorrhea after combination hormonal contraception discontinuation likely reflects a pre-existing problem (Wallach, 2000). At least 90 percent of women who previously ovulated regularly will do so within 3 months after discontinuance of oral contraceptives.

There is no evidence that COCs are teratogenic with the exception of sex organ development (Briggs, 2002). Women should be counseled regarding these findings. Many discontinue their pills because of teratogenicity fears when menses are late, and they then become pregnant.

Lactation

There are limited data on the interaction of COCs and lactation. Minute quantities of the hormones are excreted in the breast milk, but no adverse effects on infants have been noted. There is concern that these agents reduce the volume of breast milk, although a Cochrane Review confirmed the ambiguity of these data (Truitt, 2003). Because progestin-only oral contraceptives have little effect on lactation, they are preferred for up to 6 months in women who are exclusively breast feeding (Oral Progestins). Those who are only intermittently breast feeding should use effective contraception beginning as soon as 3 weeks postpartum (Kaunitz, 1997). According to guidelines published by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) "nursing mothers may begin using oral contraceptives as soon as their milk supply is established".

Weight Gain

There have been a few retrospective studies that have reported conflicting results regarding COCs efficacy and body weight (Brunner, 2005; Holt, 2002, 2005). To address this, Gallo and associates (2004, 2006) reviewed 42 randomized trials and the Cochrane Database. They concluded that available evidence was insufficient to determine effects of COCs on weight, but that no large effect was evident.

Other Effects

Cervical mucorrhea, likely due to cervical eversion, is fairly common in response to the estrogen component (Critchlow, 1995). The mucus at times may be irritating to the vagina and vulva. *Vaginitis* or *vulvovaginitis,* especially that caused by *Candida* species, also may develop.

Hyperpigmentation of the face and foreheadâ€"also known as *chloasma* â€"is more likely in women who demonstrated such a change during pregnancy. This is seen much less commonly with the use of low-dose estrogen formulations. As discussed, oral contraceptives may improve acne.

Uterine *leiomyomas* do not increase in size with oral contraceptive use (Wise, 2004). Low-dose estrogen formulations are not associated with *depression* , and indeed, may cause it to improve (Goldzeiher, 1995).

Multiple studies have been conducted to evaluate the relationship between the use of oral and injectable contraceptives and the risk of *HIV infection.* Although most of these have methodologic limitations, on balance they do not suggest increased risk (Stephenson, 1998). On the other hand, hormonal contraception does not *prevent* the transmission of HIV infection or any other viral infection. Consistent use of condoms for the prevention of sexually transmitted infections should be emphasized.

RISK OF DEATH

Mortality associated with oral contraceptives is rare if a woman is younger than 35, has no systemic illness, and does not smoke (see Table 5-1). Porter and associates (1987) reported only one death attributed to oral contraceptive use in nearly 55,000 woman-years from the Group Health Cooperative of Puget Sound.

POSTPARTUM USE

Women who do not breast feed may ovulate before 6 weeks after pregnancy. They do so much earlier after an early pregnancy loss or induced abortion (see Chap. 6, Resumption of Ovulation Following Miscarriage). There is an advantage, therefore, to starting oral contraceptives before the traditional 6-week postpartum examination. On the other hand, increased risks of adverse effects,

especially venous thromboembolism, might be anticipated from use of estrogen-progestin contraceptives earlier in the puerperium. The use of 35 µg or lower estrogen doses has reduced this risk greatly. Thus far, in our now extensive experience in which oral contraceptives have been started during the third week postpartum, there has been no evidence of increased morbidity or mortality.

CONTRAINDICATIONS

It could be argued that because pregnancy is usually more dangerous than oral contraception, that no contraindication to oral contraceptives should be considered absolute. Pragmatically, considering the multiplicity of alternate contraceptive methods, if a contraindication listed in Table 5-7 is present, combined COCs should probably not be prescribed, and alternative methods should be encouraged.

Table 5-7 Typical Package Insert Listing Contraindications and a Warning About the Use of Combination Oral Contraceptives

Contraindications: Combination contraceptives should not be used in women with:
Thrombophlebitis or thromboembolic disorders
History of deep vein thrombophlebitis or thrombotic disorders
Cerebrovascular or coronary artery disease
Thrombogenic cardiac valvulopathies
Thrombogenic heart arrhythmias
Diabetes with vascular involvement
Severe hypertension
Known or suspected breast carcinoma
Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia
Undiagnosed abnormal genital bleeding
Cholestatic jaundice of pregnancy or jaundice with pill use
Hepatic adenomas or carcinomas or active liver disease with abnormal liver function
Known or suspected pregnancy
Major surgery with prolonged immobilization
Warning
Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with the extent of smoking (in epidemiologic studies, 15 or more cigarettes per day was associated with a significantly increased risk), and is marked in women older than 35 years. Women who use oral contraceptives should be strongly advised not to smoke.

From Physicians Desk Reference, 2006, with permission.

That said, we must remember that most of the lists that proscribe COC use in women with chronic illnesses were arrived at intuitively and without data. An example is the use of highly effective low-dose COCs in women with systemic lupus erythematosus. While considered a contraindication to COC use, two recent randomized trials of over 300 women with lupus showed no increased adverse effects of COCs compared with placebo (Petri, 2005; SÃ¡nchez-Guerrero, 2005).

TRANSDERMAL ADMINISTRATION

The combined contraceptive approved patch (Ortho Evra, Ortho-McNeil Pharmaceutical, Raritan, NJ) is applied to the buttocks,

upper outer arm, lower abdomen, or upper torso but avoiding the breasts (Fig. 5-2). It delivers 150 µg of the progestin, norelgestromin, and 20 µg of ethinyl estradiol daily. A new patch is applied each week for 3 weeks, followed by a patch-free week to allow for withdrawal bleeding.

In a randomized trial by Audet and co-workers (2001), the patch was slightly more effective than a low-dose oral contraceptive in preventing pregnancyâ€”1.2 versus 2.2 pregnancies per 100 woman-years. Although overall well tolerated and safe, dysmenorrhea and breast tenderness were more frequent in the patch group, as was breakthrough bleeding in the first two cycles. Almost 5 percent of the patches required replacement for either complete (1.8 percent) or partial detachment (2.8 percent). In about 3 percent of women, the patch caused an application site reaction severe enough to limit continued use.

Pooled data suggest that women who weigh 90 kg or more are at increased risk for contraceptive failure. Of 15 failures reported, five women met this threshold, even though they constituted less than 3 percent of the study population (Zieman, 2002). This translates to a relative risk of failure of 16 or more.

The patch, therefore, is an effective alternative hormonal contraceptive method for women who prefer weekly application rather than daily dosing and who find a transdermal method acceptable. Its metabolic and physiologic effects should be substantively the same as with low-dose oral contraceptives, although accumulated experience is limited.

TRANSVAGINAL ADMINISTRATION

An intravaginal hormonal contraceptive ringâ€”*NuvaRing* (Organon, Roseland, NJ)â€”is a flexible polymer ring with an outer diameter of 54 mm and an inner diameter of 50 mm (Fig. 5-3). Its core contains ethinyl estradiol and the progestin, etonogestrel, which are released at rates of 15 µg and 120 µg per day, respectively. Although this results in serum hormone levels lower than comparable low-dose oral contraceptives, ovulation inhibition is complete (Mulders, 2001). It is highly effective, and in one study, the failure rate was 0.65 per 100 woman-years (Roumen, 2001).

The rings are refrigerated, and once dispensed their shelf life is 4 months (Burkman, 2002). The ring is initially placed within 5 days of the onset of menses. It is removed after 3 weeks of use for 1 week to allow withdrawal bleeding. After this, a new ring is inserted. Breakthrough bleeding is uncommon.

Almost 20 percent of women and 35 percent of men reported being able to feel the ring during intercourse. If this is bothersome, the ring may be removed for coitus, but should be replaced within 3 hours.

INTRAMUSCULAR ADMINISTRATION

There is only one combination preparation for intramuscular injection. Previously marketed in the U.S. as *Lunelle,* this contraceptive contains 25 mg of medroxyprogesterone acetate plus 5 mg of estradiol cypionate. One injection is given monthly. The drug inhibits ovulation and suppresses endometrial proliferation (Aedo, 1985). Serum estradiol values reach a peak level by 3 to 4 days postinjection and then decline, leading to withdrawal bleeding 20 to 25 days after injection (Garceau, 2000).

Only six method failures in 70,000 woman-years of use have been reported (Hall, 1994). This degree of effectiveness compares similarly with that seen following female sterilization procedures. Contraindications are similar to those for COCs as shown in Table 5-7.

In 2002, prefilled Lunelle syringes were recalled by the manufacturer due to lack of assurance of full contraceptive potency. Although still FDA-approved, this method has not since been marketed in the United States.

Progestational Contraceptives

ORAL PROGESTINS

Progestin-only pills, also known as *mini-pills,* are taken daily. Unlike COCs, they do not reliably inhibit ovulation. Rather, their effectiveness depends more on cervical mucus alterations and effects on the endometrium. Because the mucus changes do not persist beyond 24 hours, to be maximally effective it should be taken at the same time every day.

These contraceptives have not achieved widespread popularity because of a much higher incidence of irregular bleeding and a

slightly higher pregnancy rate than combination contraceptives (see Table 5-2). Improved effectiveness has been reported for married, and in a progressive fashion, older women (Guillebaud, 1985).

Benefits

Progestin-only pills have minimal if any effect on carbohydrate metabolism or coagulation, and they do not cause or exacerbate hypertension. They may be ideal for some women who are at increased risk of cardiovascular complications. This includes women with a history of thrombosis, hypertension, or migraine headaches, or who are older than 35 years and smoke. In addition, the mini-pill is often an excellent choice for lactating women. In combination with breast feeding, it is virtually 100-percent effective for up to 6 months and does not impair milk production (Betrabet, 1987; Shikary, 1987).

Disadvantages

The major drawback of progestin-only pills is contraceptive failure. With these failures, there is a relative increase in the proportion of ectopic pregnancies (Sivin, 1991). Irregular uterine bleeding is another distinct disadvantage and may manifest as amenorrhea, metrorrhagia, or prolonged periods of menorrhagia. Functional ovarian cysts develop with a greater frequency in women using these agents, although they do not usually necessitate intervention.

As discussed, one distinct disadvantage is that these contraceptives must be taken at the same or nearly the same time each day. **If a progestin-only pill is taken even 4 hours late, an additional form of contraception must be used for the next 48 hours.** Their effectiveness is decreased by medications that include anticonvulsantsâ€”phenytoin, carbamazepine, felbamate, oxcarbazepine, primidone, and topiramate; and antituberculous agentsâ€”rifampicin and rifabutin (Speroff, 2001). Women taking any of these medications should not use this form of contraception. Finally, unlike combined oral contraceptives, the mini-pill does not improve acne, and may even worsen it in some women.

Contraindications

Progestin-only pills, like other methods of contraception, are contraindicated in women with unexplained uterine bleeding or breast cancer.

INJECTABLE PROGESTIN CONTRACEPTIVES

Depot medroxyprogesterone acetate (*Depo-Provera,* Pfizer, New York, NY) and norethindrone ethanthate (*Norgest*) have been used effectively worldwide for many years. Depo-Provera, although available for many years before, was approved in 1992 for contraceptive use in the United States. Norgest is not yet available. Their mechanisms of action are similar to those for oral agents: ovulation inhibition, increased cervical mucus viscosity, and stimulation of an endometrium unfavorable for ovum implantation (Mishell, 1996).

Depot medroxyprogesterone is injected deeply into the upper outer quadrant of the buttock or into the deltoid muscles without massage to ensure that the drug is released slowly. The usual dose is 150 mg every 90 days. An additional contraceptive method should be used for at least 2 weeks after the initial injection.

Recently, *depo-subQ provera 104* has become available. It contains 104 mg of medroxyprogesterone acetate that is injected subcutaneously every 90 days. In three clinical studies, no pregnancies were detected among 2,042 women using it for up to 1 year.

Benefits and Disadvantages

Injected progestins have contraceptive effectiveness comparable with or better than COCs, a long duration of action, and minimal to no impairment of lactation (American College of Obstetricians and Gynecologists, 2000a). Iron-deficiency anemia is less likely in long-term users, probably as a result of amenorrhea, which develops in 80 percent of women after 5 years (Gardner, 1970).

The principal disadvantages of depot progestins include irregular menstrual bleeding and prolonged anovulation after discontinuation resulting in delayed fertility resumption. Cromer and associates (1994) reported that a fourth of women discontinued its use in the first year because of irregular bleeding. After the injections are stopped, a fourth of women will not resume regular menses for up to a year (Gardner, 1970).

The reported risks of breast cancer are conflicting. Skegg and colleagues (1995) pooled the results of the New Zealand and WHO case-control studies. These studies included almost 1,800 women with breast cancer and 14,000 controls. Within the first 5 years of use, the contraceptive was associated with a twofold risk of cancer, but overall the risk was not increased. Cervical and hepatic malignancies do not appear to be increased, and the risk of ovarian and endometrial cancers is decreased (Earl, 1994; Kaunitz, 1996). The risk of cervical carcinoma in situ may be increased (Thomas, 1995).

Although weight gain is often attributed to depot medroxyprogesterone, conclusive evidence is lacking (Mainwaring, 1995; Moore, 1995; Taneepanichskul, 1998). Breast tenderness is reported by some users, as is depression, although a causal link for the latter has not been demonstrated.

One concern in long-term users of both intramuscular and subcutaneous depot medroxyprogesterone is loss of bone mineral density (Scholes, 1999). It is probably most relevant for teenagers because bone density increases most rapidly from age 10 to 30 (Cromer, 1996; Sulak, 1999). Reassuringly, bone loss appears to be reversible after discontinuation of the drug (Cundy, 1994). The addition of a "black box" warning to clinicians for these two injectable progestins has been added and explains that they should be used for longer than 2 years only if other methods of birth control are inadequate.

PROGESTIN IMPLANTS

In these systems, a progestin is delivered by a subdermally implanted device containing the drug and coated with a compound to prevent fibrosis. Currently, there are two preparations. The *Norplant System* (Wyeth, Madison, NJ) contains levonorgestrel in six silastic containers. Its contraceptive effectiveness persists for 60 months, at which point the system should be removed (Hatcher, 1998). Despite its effectiveness, safety, and patient satisfaction, use of this excellent contraceptive waned dramatically following law suits involving this method. Allegations of illness related to the silicone-based rods created a climate of litigation around this system, and currently it is no longer available. A fund has been established by the manufacturer to ensure medical access for removal.

The *Implanon System* (Organon, Roseland, NJ) is a single rod subdermal implant with 68 mg of the progestin, etonogestrel, and has an ethylene vinyl acetate co-polymer cover (Fig. 5-4). Similar to the Norplant System, daily release of etonogestrel causes ovulation suppression, cervical mucus thickening, and an atrophic endometrium.

EMERGENCY CONTRACEPTION

Many women present for contraceptive care following consensual but unprotected sexual intercourse, and in some cases aggravated sexual assault. In these situations, there are a number of methods that if used correctly, will substantially decrease the likelihood of an unwanted pregnancy.

Hormonal Emergency Contraception

This is also known as the *morning after pill,* or the *Yuzpe method.* There are two hormonal methods currently available. The Yuzpe method consists of commonly available COCs, and the other is a progestin-only productâ€"*Plan B* (Barr Pharmaceuticals, Pomona, NY). A third product, consisting of an estrogen and progestin combinationâ€"*Preven,* was approved by the FDA in 1998, but withdrawn from the market in 2004.

Access to emergency contraception has not been universal. Trussell and colleagues (2000) found that only 75 percent of attempts to access care through the Emergency Contraception Hotline were successful. Clinicians can register to be included as a resource and women can obtain referrals on the Hotline at 1-888-NOT-2-LATE (888-668-2528), the Emergency Contraception Website (http://www.not-2-late.com), or Pastillas Anticonceptivas de Emergencia (http://www.en3dias.org.mx).

ESTROGEN-PROGESTIN COMBINATIONS

A number of combined oral contraceptive regimens were approved in 1997 by the FDA for use as emergency contraception (Table 5-8). Tablets are taken within 72 hours of intercourse, followed 12 hours later by a second dose. Regimens are more effective the sooner they are taken after unprotected sex.

[a] Treatment consists of two doses taken 12 hours apart. Use of an antiemetic agent before taking the medication will lessen the risk of nausea, which is a common side effect.

From American College of Obstetricians and Gynecologists, 2005a, with permission.

Emergency hormone contraceptive regimens are highly effective and decrease the risk of pregnancy by up to 94 percent (American College of Obstetricians and Gynecologists, 2005a). Thus, if 100 women had unprotected intercourse during the second to third

week of their menstrual cycle, eight would be expected to conceive. With appropriate use of one of these regimens, only two would actually conceive.

Nausea and vomiting are major problems due to high-dose estrogen in these regimens. Trussell and associates (1998a) reported nausea in 50 percent of women and vomiting in 20 percent. For this reason, we routinely prescribe an oral antiemetic at least 1 hour before each dose. Raymond and colleagues (2000) conducted a randomized trial and found that 1-hour pretreatment with 50-mg meclizine given orally decreased nausea substantially. Ragan and associates (2003) found that 10 mg of oral metoclopramide decreased both nausea and cramping compared with placebo. If a woman vomits within 2 hours of a dose, the dose must be repeated.

PROGESTINS ONLY

Plan B consists of two tablets each containing 0.75 mg levonorgestrel. The first dose is taken within 72 hours of unprotected coitus and the second dose 12 hours later (see Table 5-8). According to the Task Force on Postovulatory Methods of Fertility Regulation (1998), mini-pill progestins are more effective than combination estrogen-progestin pills. This regimen resulted in a crude pregnancy rate of 1.1 compared with 3.2 percent in a similar group of women treated with the Yuzpe regimen. Moreover, Ellertson and colleagues (2003) reported a 55-percent pregnancy prevention rate if Plan B was taken as late as 4 to 5 days after unprotected intercourse.

In 2006, the FDA approved Plan B as an over-the-counter option for women aged 18 years and older (U. S. Food and Drug Administration, 2006). As a result, in nine states, women older than 18 may now obtain Plan B without a prescription. These include Alaska, California, Hawaii, Maine, Massachusetts, New Hampshire, New Mexico, Washington and Vermont.

MECHANISM OF ACTION

The major mechanism of action is inhibition or delay of ovulation (U.S. Food and Drug Administration, 1997). Other suggested mechanisms include alteration of the endometrium to prevent implantation, sperm penetration, and tubal motility (American College of Obstetricians and Gynecologists, 2005a). **Established pregnancies are not harmed.** When evaluated in animals, emergency contraception does not prevent ovulation or implantation (Croxatto, 2003; Marions, 2004).

Copper-Containing Intrauterine Devices

Fasoli and co-workers (1989) summarized nine studies that included results from 879 women who accepted some type of copper-containing intrauterine device (IUD) as a sole method of postcoital contraception. The only pregnancy reported aborted spontaneously. Trussell and Stewart (1998) reported that when an IUD was inserted up to 5 days after unprotected coitus, the failure rate was 1 percent. A secondary advantage is that this method also puts in place an effective 10-year method of contraception.

Mifepristone (RU 486) and Epostane

These medications are discussed in Chapter 6, Medical Abortion. They should be ideal for postcoital contraception, either by blocking progesterone production (epostane), or interfering with its action (mifepristone). Implantation prevented by either mechanism results in so-called *menstrual induction.*

Ashok and colleagues (2002) reported that a single 100-mg tablet of mifepristone was more effective than the Yuzpe regimen with crude pregnancy rates of 0.6 versus 3.6 percent, respectively. There were also fewer side effects with mifepristone. Although hormonal regimens must be used within 72 hours of unprotected intercourse, mifepristone is effective up to 17 days after intercourse (Weiss, 1993).

Failure of Emergency Contraception

If menstruation is delayed for more than 3 weeks past its expected onset, pregnancy is likely. Any postcoital contraceptive method is associated with failures, which likely can be reduced by employing a barrier technique until the next menses to prevent fertilization after use of the postcoital method.

MECHANICAL METHODS OF CONTRACEPTION

Intrauterine Contraceptive Device

At one time in the United States, approximately 7 percent of sexually active women used an intrauterine device (IUD) for contraception. The two devices currently approved for use in this country are shown in Fig. 5-5. Unwanted pregnancies during the first year of perfect use are 0.6 percent for the copper-containing *ParaGard T 380A* (Duramed Pharmaceuticals, Pomona, NY) and 0.1 percent for the levonorgestrel-containing *Mirena* (Bayer HealthCare Pharmaceuticals, Wayne, NJ). Respective typical failure rates are 0.8 percent and 0.1 percent.

FIGURE 5-5

With new information on safety, the IUD is once again gaining in popularity for several reasons:

1. Both ParaGard and Mirena are "use and forget" effective reversible contraceptive methods that do not have to be replaced for 10 and 5 years, respectively.
2. It is now better established that the major actions of IUDs are contraceptive and not abortifacient.
3. The risk of pelvic infections is markedly reduced with the currently used monofilament string along with techniques to ensure safer insertion.
4. The risk of an associated ectopic pregnancy has been clarified, to show that the contraceptive effect decreases the absolute number of ectopic pregnancies by half, compared with women not using contraception (World Health Organization, 1985, 1987). That said, with contraceptive failure, pregnancy is still more likely to be ectopic (Furlong, 2002).
5. Legal liability appears to be lessened because the FDA currently classifies available devices as drugs (Mishell, 1997). As such, manufacturers must provide product information to be read by women prior to insertion. Signed consent forms that include a reasonable listing of risks and benefits are also required.

TYPES OF DEVICES

Those that are *chemically inert* are composed of a nonabsorbable material, most often polyethylene, and impregnated with barium

sulfate for radiopacity. *Chemically active* devices have continuous elution of copper or a progestational agent. At the present time, only chemically active IUDs are available.

Levonorgestrel-Containing Intrauterine Device

The Mirena device releases levonorgestrel into the uterus at a relatively constant rate of 20 μg/d, which reduces the systemic effects of the progestin. It is a T-shaped polyethylene structure that has its stem wrapped with a cylinder made of polydimethylsiloxane and levonorgestrel. A permeable membrane surrounds the mixture to regulate the rate of hormone release. A monofilament brown polyethylene thread is attached to a small loop at the distal end of the device's vertical body.

Copper-Containing Intrauterine Device

The ParaGard T 380A device is composed of polyethylene with barium sulfate. The stem is wound with 314 mm^2 of fine copper wire, and the arms each have 33-mm^2 copper bracelets; these total 380 mm^2 of copper. Two strings extend from the base of the stem (see Fig. 5-5). Originally blue, the strings now are white.

MECHANISMS OF ACTION

These have not been defined precisely and are the subject of ongoing controversy. Interference with successful implantation of the fertilized ovum, which at one time was believed to be the main mode of action, is less important than prevention of fertilization (Mishell, 1997; Stanford, 2002). The intense local inflammatory response induced in the uterus, especially by copper-containing devices, leads to lysosomal activation and other inflammatory actions that are spermicidal (Alvarez, 1988; Ortiz, 1987). In the unlikely event that fertilization does occur, the same inflammatory actions are directed against a blastocyst. And finally, the endometrium is transformed into a hostile site for implantation.

In long-time progestin device users, the endometrium becomes atrophic. There may be a major effect in preventing fertilization by spermicidal action, or speeding ovum transport through the fallopian tube, or both (Alvarez, 1988; Ortiz, 1987). The progestin may interfere with sperm penetration through thickened cervical mucus, and it inhibits ovulation, but not consistently (Nilsson, 1984).

EFFECTIVENESS

One-year continuation rates are equal to those of oral contraceptives. This almost certainly is due to the effectiveness of IUDs and a once-only approach to contraception. Their effectiveness is similar overall to that of tubal sterilization (American College of Obstetricians and Gynecologists, 2003a). Importantly, the unintended pregnancy rate decreases progressively after the first year of use. The levonorgestrel-containing Mirena device has a typical user failure rate of 0.1 percent, which is lower than the copper-containing ParaGard (Rowe, 1992).

OTHER BENEFICIAL EFFECTS

The Mirena device reduces menstrual blood loss and can even be used to treat menorrhagia (see Chap. 8, Levonorgestrel-Containing Intrauterine System) (American College of Obstetricians and Gynecologists, 2006). Moreover, reduced blood loss is often associated with a reduction in dysmenorrhea. Despite their higher up-front costs, the overall extended use of IUDs makes their long-term cost effectiveness competitive with other forms of contraception. Women with contraindications to COCs can often use these devices. The device is also reported to reduce the incidence of pelvic infections (Toivonen, 1991; van den Hurk, 1999).

ADVERSE EFFECTS

Numerous complications have been described with use of various intrauterine devices. For the most part, however, common side effects with these two devices have not been serious, and serious side effects have not been common. Moreover, with extended use and advancing user age, unintended pregnancy, expulsion, and bleeding complications decrease in frequency.

Uterine Perforation

The earliest adverse effects are those associated with insertion. They include clinically apparent or silent *uterine perforation,* which occurs while sounding the uterus or during insertion. Perforations occur at a rate of approximately 1 per 1,000 insertions (World Health Organization, 1987). Although devices may migrate spontaneously into and through the uterine wall, most perforations occur, or at least begin, at the time of insertion.

Cramping and Bleeding

It is common for women to have uterine cramps and some bleeding soon after IUD insertion. These persist for a variable time. Cramping can be minimized by administering a nonsteroidal anti-inflammatory agent approximately 1 hour prior to insertion. Any associated increase in menstrual cramping may also be treated with these drugs.

Menorrhagia

Menstrual blood loss is commonly doubled with use of the ParaGard device (see Chap. 8, Copper-Containing Intrauterine Device). Because this may cause iron-deficiency anemia, iron salts are given prophylactically and most providers perform hemograms annually. Menorrhagia is a troubling side effect, and approximately 10 to 15 percent of women using the copper device have it removed for this problem (Hatcher, 1998). In contrast, the Mirena device is associated with progressive amenorrhea, which is reported by 30 percent of women after 2 years and by 60 percent after 12 years (Ronnerdag, 1999).

Infection

A variety of *pelvic infections,* in some cases fatal, have been described with intrauterine devices. These include *septic abortion,* which mandates immediate curettage. *Tubo-ovarian abscesses* â€”sometimes unilateralâ€”have been described. With suspected infection, antimicrobial treatment is given. There is mixed evidence with upper genital tract infection whether the IUD should be removed after therapy has been initiated (Grimes, 2000).

Historically, there has been much debate regarding appropriate candidates for IUD use. For example, its use was discouraged for women under the age of 25 or those of low parity. Recent well-designed studies indicate that sexual behavior and sexually transmitted disease history are the important risk factors. The FDA has correspondingly made changes to the package insert so that no longer are the restrictions based on sexual behavior aloneâ€”appropriate counseling and candidate selection are most important. Thus, nulliparous and multiparous women in mutually monogamous relationships may safely use the IUD (Speroff, 2001).

The major risk of infection is at the time of insertion and does not increase with long-term use. There is also a small increased risk of pelvic infection for up to the first 20 days (Farley, 1992). There currently is no evidence that prophylactic antibiotic administration at the time of IUD insertion reduces the risk of infection in women at low risk for sexually transmitted infections (American College of Obstetricians and Gynecologists, 2001; Sinei, 1990; Walsh, 1998). With long-term use of current devices, pelvic infection rates are comparable to those in oral contraceptive users. Any infection after 45 to 60 days should be considered sexually transmitted and appropriately treated (see Chap. 3, Treatment).

Fiorino (1996) cited an incidence of 7 percent of *Actinomyces* species seen on cytology smears from women using IUDs compared with less than 1 percent in nonusers. In some cases, pelvic inflammatory disease may develop (Dunn, 2006). Women who developed a pelvic abscess caused by this organism had used the device for a mean of 8 years before symptoms were noted. In the absence of symptoms, the incidental finding of *Actinomyces* by cytology has uncertain significance. The American College of Obstetricians and Gynecologists (2005c) reviewed treatment options, which include expectant management, an extended course of antibiotics, IUD removal, and antibiotics plus IUD removal. It was concluded that if symptomatic infection develops in women who harbor *Actinomyces,* then the IUD should be removed and antibiotic therapy given.

Pregnancy with Retained IUD

Early identification of pregnancy is important in these women. Up to about 14 weeks, the tail of the device may be visible through the cervix. If seen, it should be removed. This will reduce subsequent complications if the woman chooses to continue the pregnancy. For example, Tatum and co-workers (1976) reported the miscarriage rate to be 54 percent with the device left in situ compared with 25 percent if promptly removed. Second-trimester miscarriages with an IUD in place are more likely to be septic than those without an IUD (Lewit, 1970; Vessey, 1974). Sepsis may be fulminant and often fatal. With the device left in, the frequency of low birthweight, chiefly from preterm delivery, was 20 percent, compared with about 5 percent with removal. Fetal malformations have not been reported to be increased with a device in place (Vessey, 1979).

If the tail is not visible, attempts to locate and remove the device may result in pregnancy loss. Some have successfully used sonography to assist in the removal of devices without visible strings. Because of these risks, a woman should be offered the option

of pregnancy termination. With continuing pregnancy, it is reasonable to not attempt removal. Women pregnant with a retained device who demonstrate any evidence of uterine infection are treated with intensive antibiotic therapy and prompt uterine evacuation. In women who give birth with a device in place, appropriate steps should be taken at delivery to identify it and ensure its removal.

Ectopic Pregnancy

Although most intrauterine pregnancies are prevented, the device provides less protection against extrauterine implantation (Furlong, 2002). This is discussed in Chapter 7, Risk Factors.

CONTRAINDICATIONS

Those of the manufacturers are listed in Table 5-9. Because the progestin released by the Mirena device may inhibit tubal mobility, a previous ectopic pregnancyâ€”or predisposing risk factorsâ€”are considered contraindications.

Table 5-9 Contraindications to Use of an Intrauterine Device

General

1. Pregnancy or suspicion of pregnancy
2. Abnormalities of the uterus resulting in distortion of the uterine cavity
3. Acute pelvic inflammatory disease or a history of pelvic inflammatory disease unless there has been a subsequent uterine pregnancy
4. Postpartum endometritis or infected abortion in the past 3 months
5. Known or suspected uterine or cervical neoplasia, or unresolved abnormal cytological smear
6. Genital bleeding of unknown etiology
7. Untreated acute cervicitis or vaginitis, including bacterial vaginosis, until infection is controlled
8. Woman or her partner has multiple sexual partners
9. Conditions associated with increased susceptibility to infections with microorganisms. These include, but are not limited to, leukemia, acquired immune deficiency syndrome, and intravenous drug abuse
10. History of ectopic pregnancy or condition that would predispose to ectopic pregnancy
11. Genital actinomycosis
12. A previously inserted intrauterine device that has not been removed

ParaGard T 380A, because of its copper content, should not be inserted when one or more of the following conditions exist:

1. Wilson disease
2. Copper allergy

Mirena insertion is contraindicated when one or more of the following conditions exist:

1. Hypersensitivity to any component of this product
2. Known or suspected carcinoma of the breast
3. Acute liver disease or tumor

PROCEDURES FOR INSERTION

The FDA requires that before an intrauterine device is inserted, the woman must be given a brochure detailing the side effects and apparent risks from its use. Most devices have a special inserter, usually a sterile graduated plastic tube or sleeve into which the device is drawn just before insertion (Fig. 5-6). Timing of insertion influences the ease of placement as well as the pregnancy and

expulsion rates. Insertion near the end of normal menstruation, when the cervix is usually softer and the canal somewhat more dilated, may aid insertion and at the same time exclude early pregnancy. Insertion, however, need not be limited to this time. For a woman who is sure she is not pregnant and does not want to be pregnant, insertion may be carried out at anytime.

Insertion of ParaGard T 380A using the withdrawal technique.

Insertion immediately postpartum is done in some countries. Grimes and colleagues (2001) surveyed the Cochrane Database and concluded that it is safe to do so, however, the expulsion rate and possibly the pregnancy rates are higher than later insertion. The recommendation has been made, therefore, to withhold insertion for at least 6 to 8 weeks to reduce expulsion rates and to minimize the risk of perforation. In our extensive experience, however, insertion at 2 weeks has not led to perforation or expulsion rates significantly higher than for later insertion. In the absence of infection, the device may be inserted immediately after early miscarriage or abortion. Women delivered at Parkland Memorial Hospital are seen at 2 to 3 weeks postpartum. Our policy is to insert IUDs at 6 weeks or sooner if involution is complete.

Technique

A satisfactory technique for insertion of the ParaGard device is as follows:

1. Determine whether there are contraindications, counsel the woman regarding various problems associated with device use, and obtain written consent.
2. Administer a nonsteroidal anti-inflammatory agent, with or without codeine, to allay cramps.
3. Perform a pelvic examination to identify the position and size of the uterus and adnexa. If abnormalities are found, they should be evaluated, as they may contraindicate the device. Mucopurulent discharge and significant vaginitis should be appropriately treated and resolved before insertion.
4. The cervical surface is cleansed with an antiseptic solution, and a tenaculum is placed on the cervical lip. The uterus is sounded, and the blue plastic flange on the outside of the inserter tube is positioned from the tube tip to reflect this depth.
5. **The device should not be loaded into its inserter tube more than 5 minutes before insertion.** The malleable arms tend to retain the "memory" of the inserter.
6. The inserter tube, with the IUD loaded, is passed into the endometrial cavity. When the blue flange abuts the cervix, insertion stops.

7. To release the arms of the ParaGard, hold the solid white rod within the tube steady and withdraw the insertion tube no more than 1 cm. This releases the arms high in the uterine fundus.
8. Gently and carefully move the insertion tube upward toward the top of the uterus until slight resistance is felt. This will ensure placement of the T at the highest possible position within the uterus.
9. Hold the insertion tube steady and withdraw the solid white rod.
10. Gently and slowly withdraw the tube from the cervical canal. Only the threads should be visible protruding from the cervix. Trim the threads so that 3 to 4 cm protrude into the vagina. Note the length of the threads in the chart.

If you suspect that the device is not in the correct position, check placement, using sonography if necessary. If it is not positioned completely within the uterus, remove it and replace it with a new device. Do not reinsert an expelled or partially expelled ParaGard device.

11. Cut the marker tail 2 cm from the external os, remove the tenaculum, and observe for bleeding from the tenaculum puncture sites. If there is no bleeding, remove the speculum.
12. Advise the woman to promptly report any apparent adverse effects.

The Mirena device requires some modifications to this technique . These are detailed in its package insert. Specifically, the arms of the device are released in the uterus *prior* to advancing it 1.5 to 2 cm to the fundus. This is accomplished by setting the flange to the sounded uterine depth, and using it to gauge, based on its 1.5- to 2-cm distance from the external os, when to release the arms. A detailed description follows:

1. Pick up the inserter containing the Mirena and carefully release the threads from behind the slider so that they hang freely.
2. Ensure that the slider is in the furthermost position away from youâ€”positioned at the top of the handle nearest the device.
3. While looking at the insertion tube, align the arms of the system horizontally.
4. Pull on both threads to draw the Mirena system into the insertion tube. Note that the knobs at the end of the arms now cover the open end of the inserter.
5. Fix the threads tightly in the cleft at the end of the handle.
6. Set the flange to the depth measured by the sound.
7. Mirena is now ready to be inserted.
8. Hold the slider firmly in the furthermost positionâ€”at the top of the handle. Grasp the cervix with the tenaculum and apply gentle traction to align the cervical canal with the uterine cavity. Gently insert the inserter tube into the cervical canal and advance the insertion tube into the uterus until the flange is situated at a distance of about 1.5 to 2 cm from the external cervical os to give sufficient space for the arms to open. **Do not force the inserter.**
9. While holding the inserter steady, release the arms of the device by pulling the slider back until the top of the slider reaches the mark, the raised horizontal line on the handle.
10. Push the inserter gently into the uterine cavity until its flange touches the cervix. The device should now be in the fundal position.
11. Holding the inserter firmly in position, release the device by pulling the slider down all the way. The threads will be released automatically.
12. Remove the inserter from the uterus. Cut the threads to leave about 2 to 3 cm visible outside the cervix.
13. If you suspect that the system is not in the correct position, check placement, using sonography if necessary. Remove the device if it is not positioned completely within the uterus. Do not reinsert a removed system.

EXPULSION

Loss of the device from the uterus is most common during the first month. The woman should be instructed to palpate the strings protruding from the cervical os by either sitting on the edge of a chair or squatting down and then advancing a finger into the vagina until the cervix is reached. The woman should be examined again in about a month, usually after menses, for appropriate

placement by identifying the tail protruding from the cervix. Barrier contraception may be desirable during this interval, especially if a device has been expelled previously.

LOST DEVICE

When the tail cannot be visualized, the device may have been expelled, or it may have perforated the uterus. In either event, pregnancy is possible. Conversely, the tail simply may be in the uterine cavity along with a normally positioned device. Often, gentle probing of the uterine cavity with a Randall stone clamp or a rod with a terminal hook will retrieve the string. **Never assume that the device has been expelled unless it was seen** .

When the tail is not visible and the device is not felt by gentle probing of the uterine cavity, sonography can be used to image the uterine cavity. If these findings are negative or inconclusive for device visualization, then a plain radiograph of the abdomen and pelvis may be obtained with a uterine sound inserted into the endometrial cavity for orientation. Instillation of radiocontrast for hysterography may also be done. Hysteroscopy is yet another alternative. Obviously none of these invasive maneuvers should be performed if a woman is pregnant and does not desire termination.

An open device of inert material, such as the Lippes Loop, located outside the uterus may or may not do harm. Large and small bowel perforations as well as bowel fistulas have been reported remote from insertion. An extrauterine copper-bearing device induces an intense local inflammatory reaction and adhesions. Chemically inert devices usually are removed easily from the peritoneal cavity by laparoscopy or colpotomy. Copper-bearing devices are more firmly adhered and laparotomy may be necessary.

A device may penetrate the uterine wall to varying degrees (Fig. 41-35.5). Part of the device may extend into the peritoneal cavity while the remainder is firmly fixed in the myometrium. Devices also can penetrate into the cervix and protrude into the vagina.

Replacement

The ParaGard device is approved for 10 years of continuous use and the Mirena device for 5 years.

Barrier Methods

For many years, condoms, vaginal spermicidal agents, and vaginal diaphragms have been used for contraception with variable success as shown in Table 5-2.

MALE CONDOM

Most condoms are made from latex rubber. Less commonly, polyurethane or the cecum of lambs is used. Condoms provide effective contraception, and their failure rate with strongly motivated couples has been as low as 3 or 4 per 100 couple-years of exposure (Vessey, 1982). Generally, and especially in the first year of use, the failure rate is much higher (see Table 5-2).

When used properly, condoms provide considerable but not absolute protection against a broad range of sexually transmitted diseases, including chlamydial, herpesvirus, and human immunodeficiency virus infection, as well as gonorrhea, syphilis, and trichomoniasis. They also may prevent and ameliorate premalignant cervical changes, probably by blocking transmission of human papillomavirus (Winer, 2006).

The contraceptive effectiveness of the condom is enhanced appreciably with a reservoir tip. Agents used for lubrication should be water based because oil-based products destroy latex condoms and diaphragms (Waldron, 1989). Speroff and Darney (2001) emphasize the following key steps to ensure maximal condom effectiveness:

1. It must be used with every coital act.
2. It should be placed before contact of the penis with the vagina.
3. Withdrawal must occur with the penis still erect.
4. The base of the condom must be held during withdrawal.
5. Either an intravaginal spermicide or a condom lubricated with spermicide should be employed.

Latex Sensitivity

Some individuals are extremely sensitive to latex. Condoms made from lamb intestines, also known as *natural skin* or *lambskin*

condoms, are effective, but they do not provide protection against infection. Because of this, a nonallergenic condom was developed using synthetic thermoplastic elastomer such as polyurethane used in surgical gloves (Mason, 1992). Polyurethane condoms are effective against sexually transmitted diseases, but have a significantly higher breakage and slippage rate than latex condoms (Frezieres, 1998; Waldron, 1991). In a randomized trial of 901 couples, Steiner and colleagues (2003) documented breakage and slippage at a rate of 8.4 percent with polyurethane condoms versus 3.2 percent with latex. Respective 6-month typical pregnancy probabilities were 9.0 versus 5.4 percent, respectively.

FEMALE CONDOM (VAGINAL POUCH)

These devices prevent pregnancy and sexually transmitted diseases. They are manufactured in many countries under different names. One brand available in the United States is the *FC Female Condom* (Mayer Laboratories, Oakland, CA), which is a polyurethane sheath with a flexible polyurethane ring at each end (Fig. 5-7). The open ring remains outside the vagina, and the closed internal ring is fitted under the symphysis like a diaphragm (Fig. 5-8). In vitro tests have shown the condom to be impermeable to human immunodeficiency virus, cytomegalovirus, and hepatitis B virus. It has a 0.6 percent breakage rate. The slippage and displacement rate is about 3 percent, compared with up to 8 percent for polyurethane male condoms. It has an acceptability rate of about 60 percent for women and 80 percent for men. The pregnancy rate is higher than with the male condom (see Table 5-2).

SPERMICIDES AND MICROBICIDES

These contraceptives are marketed variously as creams, jellies, suppositories, film, and foam in aerosol containers (Fig. 5-9). They are used widely in this country, especially by women who find other methods unacceptable. They are useful especially for women who need temporary protection, for example during the first week after starting oral contraceptives or while nursing. Most agents can be purchased without a prescription.

Vaginal contraceptive film.

Spermicides work by providing a physical barrier to sperm penetration as well as a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9. **Spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse** . Their duration of maximal effectiveness is usually no more than 1 hour. Thereafter, they must be reinserted before repeat intercourse. Douching should be avoided for at least 6 hours after intercourse.

High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. Even if inserted regularly and correctly, however, foam preparations probably result in 5 to 12 pregnancies per 100 woman-years of use (Trussell, 1990). Spermicides are not teratogenic (Briggs, 2002).

Spermicides available in the United States that primarily contain nonoxynol-9 do not provide protection against sexually transmitted infections. In randomized trials, Roddy and colleagues (1998) compared nonoxynol-9, with and without condom use, and found no additional protective effects against gonorrhea, or chlamydial or HIV infection from this spermicide. Schreiber and associates (2006) recently showed that long-term use of nonoxynol-9 had minimal effects on vaginal flora.

In contrast, there is currently much interest in combination spermicides/microbicides because they are a female-controlled contraceptive method that can also protect against sexually transmitted diseases, including HIV. Shown in Table 5-10 are a number

that are under investigation. Those in the surfactant class destroy the sperm membrane as well as any viral or bacterial pathogens by disrupting their outer envelopes or membranes. Second-generation microbicides fortify natural defenses by maintaining an acidic pH or maintaining presence of antibodies and enhancing antimicrobial peptides. They also serve to maintain a hostile vaginal environment. Third-generation microbicides work as topical antiretroviral agents. Palliser and colleagues (2006) described the use of RNA interference (RNAi) to prevent herpes simplex virus 2 vaginal mucosal infections in mice. This raises possibilities of their use in microbicides (Johnson, 2006).

DIAPHRAGM PLUS SPERMICIDE

The diaphragm consists of a circular rubber dome of various diameters supported by a circumferential metal spring (Fig. 5-10). It can be very effective when used in combination with spermicidal jelly or cream. The spermicide is applied to the cervical surface centrally in the cup and along the rim. The device is then placed in the vagina so that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. At the same time, the centrally placed

spermicidal agent is held against the cervix by the diaphragm. When appropriately positioned, the rim is lodged deep in the posterior vaginal fornix, and the opposite rim lies in close proximity to the inner surface of the symphysis immediately below the urethra (Fig. 5-11). If the diaphragm is too small, it will not remain in place. If too large, it will be uncomfortable when forced into position. Because the variables of size and spring flexibility must be specified, the diaphragm is available only by prescription (Allen, 2004).

A diaphragm in place creates a physical barrier between the vagina and cervix, and importantly, provides for intimate contact between the contraceptive jelly or cream and the cervix.

The diaphragm and spermicidal agent can be inserted hours before intercourse, but if more than 2 hours elapse, additional spermicide should be placed in the upper vagina for maximum protection and be reapplied before each coital episode. The diaphragm should not be removed for at least 6 hours after intercourse. Because *toxic shock syndrome* has been described following its use, the diaphragm should not be left in place for longer than 24 hours (see Chap. 3, Toxic Shock Syndrome).

The diaphragm requires a high level of motivation for proper use. Vessey and colleagues (1982) reported a pregnancy rate of only 1.9 to 2.4 per 100 woman-years for motivated users. In a small study, Bounds and associates (1995) reported a much higher failure rate of 12.3 per 100 woman-years. The unintended pregnancy rate is lower in women older than 35 years than in those younger than 30.

Diaphragm use results in a lower incidence of sexually transmitted diseases compared with condom use (Rosenberg, 1992). Conversely, there is a slight increase in the rate of urinary infections with this method (Hatcher, 2004). A diaphragm may not be an effective choice for women with significant pelvic organ prolapse. Prolapse may result in unstable diaphragm positioning and expulsion.

CONTRACEPTIVE SPONGE

Off the market for 8 years in the United States, the *Today* contraceptive sponge (Allendale Pharmaceuticals, Allendale, NJ) is again available. It is sold over the counter, and consists of a nonoxynol-9 impregnated polyurethane disc which can be inserted up to 24 hours prior to intercourse (Fig. 5-12). After moistening, it is placed directly against the cervix. While in place, it provides contraception regardless of the frequency of coitus. It should remain in place for 6 hours after intercourse. Although perhaps more convenient, it is less effective than the diaphragm and condom (see Table 5-2).

CERVICAL CAP

The *Prentif* cavity-rim cervical cap is a flexible, cup-like device, made of natural rubber that is fitted around the base of the cervix (Fig. 5-13A). It can be self-inserted and allowed to remain in place for up to 48 hours. It should be used with a spermicide applied once at insertion. If properly fitted and used correctly, the cap is comparable in effectiveness to the diaphragm (Bernstein, 1982; Richwald, 1989). The cap is relatively costly, and in practice, incorrect fitting or improper placement make it less effective overall than the diaphragm and spermicide (see Table 5-2). Due to lack of interest and a small market share, the Prentif cap is no longer manufactured in the United States but it is available from European manufacturers.

LEA'S SHIELD

This is a reusable, washable, barrier made of silicone which is placed against the cervix (Fig. 5-13B). The device comes in one size which simplifies the fitting process. *Lea's Shield* (Yama, Inc., Union, NJ) protects against pregnancy and sexually transmitted infections. It may be inserted any time prior to intercourse and must be left in place for at least 8 hours after. When used with spermicide, and adjusted for age, the reported 6-month life table pregnancy rate was 5.6 per 100 users (Mauck, 1996).

FERTILITY-AWARENESS BASED METHODS

This is defined by the World Health Organization as a method that involves identification of the fertile days of the menstrual cycle. The couple may then avoid intercourse or use a barrier method during those days. The comparative efficacy of fertility-awareness based methods remains unknown (Grimes, 2004). Clearly, proper instruction is critical and complex charting is involved. These charts, as well as detailed advice, are available from the National Fertility Awareness and Natural Family Planning Service for the United Kingdom (http://www.fertilityuk.org) and The Natural Family Site, BYG Publishing (http://www.bygpub.com/natural).

Standard Days Method

This method, developed by the Institute for Reproductive Health at Georgetown University, is based on self-reported regular monthly cycles of 26 to 32 days during which users avoid unprotected intercourse during cycle days 8 through 19. Women who use the *standard days method* can use *CycleBeads* (Cycle Technologies, Washington, DC) to keep track of their days (Fig. 5-14) (Arevalo, 2002).

Periodic or Rhythmic Abstinence

Because the human ovum is probably susceptible to successful fertilization for only about 12 to 24 hours after ovulation, and because sperm can live up to 6 days in the reproductive tract, periodic abstinence has intuitive appeal as a means of birth control. Pregnancy rates, however, with various methods of periodic abstinenceâ€”rhythm, natural family planning, or fertility-awareness based methodsâ€”have been estimated from 5 to 40 per 100 woman-years. Put another way, the unwanted pregnancy rate during the first year of use is approximately 20 percent (see Table 5-2).

CALENDAR RHYTHM METHOD

Ovulation most often occurs about 14 days before the onset of the next menstrual period, and unfortunately, not necessarily 14 days *after* the onset of the last menstrual period. Therefore, the *calendar rhythm method* is not reliable. The International Planned Parenthood Federation (1982) concluded that "couples electing to use periodic abstinence should, however, be clearly informed that the method is not considered an effective method of family planning".

TEMPERATURE RHYTHM METHOD

The temperature rhythm method relies on *slight* changes (a sustained 0.4Â°F increase) in the morning basal body temperature that usually occurs just before ovulation (see Fig. 19-4). This method is much more likely to be successful if, during each menstrual cycle, intercourse is avoided until well after the ovulatory temperature rise. For this method to be most effective, the woman must abstain from intercourse from the first day of menses through the third day after the increase in temperature. For obvious reasons, this is not a popular method, but with excellent compliance, the unwanted pregnancy rate is only about 2 percent the first year.

CERVICAL MUCUS RHYTHM METHOD

The so-called *Billings method* depends on awareness of vaginal "dryness" and "wetness". These are the consequence of changes in the amount and quality of cervical mucus at different times in the menstrual cycle (see Chap. 19, Cervical Factors). Abstinence is required from the beginning of menses until 4 days after slippery mucus is identified. Although this method is also not popular, when it is used accurately, the first-year failure rate is only about 3 percent.

SYMPTOTHERMAL METHOD

This system combines the use of changes in cervical mucusâ€" onset of the fertile period; changes in basal body temperatureâ€"end of the fertile period; and cycle day calculations to estimate the time of ovulation. Although more complex to learn and apply, the system does not appreciably improve reliability. The use of home kits to detect luteal hormone increases in the urine on the day prior to ovulation may improve the accuracy of periodic abstinence methods (Hatcher, 2004).

SPECIAL CONSIDERATIONS FOR CONTRACEPTION

There are a number of unique circumstances that present special challenges for assuming contraceptive efficacy while minimizing undesirable effects.

Adolescents

Menarche has decreased from about age 17 in the mid-1800s to near 12 years by 2001. Reproductive function is established earlier than psychological understanding of the consequences of sexual activity. Early sexual development far too often results in intermittent spontaneous sexual encounters and a naÃ¯ve perception of the risks of pregnancy and sexually transmitted diseases (see Chap. 14, Adolescent Perceptions of Sexual Activity) (Cromer, 1996; Sulak, 1993).

Contraception is most often sought more than a year after sexual activity has begun (Mosher, 1991). Concerns about confidentiality and lack of money deter adolescents from seeking and obtaining contraception (American College of Obstetricians and Gynecologists, 2003b). Both barriers are surmountable, and in most cases, should not impede access to contraception. Indeed, in most states, minors have explicit legal authority to consent to contraceptive services. In many areas, publicly funded clinics provide free contraception to adolescents (Alan Guttmacher Institute, 2002).

COMBINATION ORAL CONTRACEPTIVES

As a method, these agents are an excellent choice for this age group because they provide effective contraception, increased bone density, and can be used to improve acne and regulate irregular menses. The obvious disadvantage is the daily requirement of pill taking.

LONG-ACTING METHODS

Injectable depot medroxyprogesterone is an effective contraceptive that also may be considered a "use and forget" method for 3 months. The disadvantages include the need for injection every 3 months, menstrual irregularities, and loss of bone mass (Sulak,

1999).

BARRIER METHODS

Despite their obvious advantage of providing some protection against sexually transmitted diseases, barrier methods are not good choices for adolescents because they require preplanning and motivation for proper use. Such methods, especially vaginal spermicides and male condoms, should be considered primarily as backup contraceptives and protective methods for sexually transmitted diseases. Intrauterine devices may be considered for adolescents who are at low risk of sexually transmitted diseases (Edelman, 1990; Prager, 2007).

Contraceptive Choices for Women Older Than 35 Years

Although fertility begins to decline at about age 35 to 40 years, there is still the risk for unwanted pregnancy and sexually transmitted diseases. Henshaw (1998) reported that half of all pregnancies in women in their 40s are unintended, and that 65 percent of these are terminated. The primary method of concern for birth control in women older than 35 is among those who smoke and who use combination hormonal contraception. This also includes women who use nicotine in any form. None of them should use COCs because the risk of myocardial infarction is increased up to 11-fold compared with similarly aged women not using oral contraceptives (Myocardial Infarction).

COMBINATION ORAL CONTRACEPTIVES

These agents are highly effective, well tolerated, provide many health benefits, and are associated with minimal risk (Beck, 1995; Speroff, 1995). According to the American College of Obstetricians and Gynecologists (2000b), healthy, nonsmoking women may use combination oral contraceptives containing less than 50 μg of estrogen until the menopause.

INJECTABLE DEPOT MEDROXYPROGESTERONE

This is a highly effective hormonal contraceptive that can also be used by some women who cannot, for medical reasons, take COCs (Speroff, 1995). Because of the association with bone loss, this method should be used with caution for longer than 2 years in perimenopausal women.

INTRAUTERINE DEVICE

This method is a logical choice for an older woman who has completed her family and is in a monogamous relationship.

BARRIER TECHNIQUES AND SPERMICIDAL AGENTS

These methods can be used either as primary or adjunct contraception. Their effectiveness improves with advancing age in those older than 40 years, likely because of diminished fertility.

Women with Medical Conditions

Pregnancies in women with medical complications often result in dangers that far exceed those seen with most forms of contraception (American College of Obstetricians and Gynecologists, 2000b). The choice of the most effective and safest method of contraception is dependent on the disease, and how it is modified by pregnancy.

Lactation

Breast feeding is important to infant health and to child spacing. For mothers who are nursing, ovulation during the first 10 weeks after delivery is unlikely (PÃ©rez, 1981). Nursing, however, is not a reliable method of family planning for women whose infants are on a daytime-only feeding schedule. **Waiting for first menses involves a risk of pregnancy because ovulation usually antedates menstruation** . Certainly, after the first menses, contraception is essential unless a woman desires pregnancy.

According to the American College of Obstetricians and Gynecologists (2000a), progestin-only oral contraceptives are the preferred choice in most cases (Benefits). Estrogen-progestin contraceptives have been assumed to possibly reduce both the rate and the duration of milk production. However, in a systematic review of randomized trials of contraceptives during lactation, Truitt and colleagues (2003) concluded that there is insufficient evidence to establish any effect of hormonal contraception on milk quality and quantity. The benefits from pregnancy prevention by use of oral contraceptives outweigh the risks.

Intrauterine devices have also been recommended for lactating, sexually active women. There is a very small increased rate of uterine perforation in lactating women who wear an IUD, perhaps from vigorous myometrial contractions caused by oxytocin release in response to suckling (Heartwell, 1983).

STERILIZATION

In the United States in 2002, surgical sterilization was the most commonly reported form of contraception in women aged 35 to 44 years (Bensyl, 2005). The number of sterilization procedures cannot be tracked accurately because most interval tubal sterilizations and vasectomies are performed in ambulatory centers. Westhoff and Davis (2000), citing data from the National Survey of Family Growth, estimate that about 700,000 tubal sterilizations are performed annually. A number of important multicenter studies of voluntary sterilization have been performed by investigators of the United States Collaborative Review of Sterilization (CREST) and the Centers for Disease Control and Prevention. Many of their observations are subsequently described.

Female Sterilization

This is the contraceptive method of choice for 28 percent of couples in the United States (American College of Obstetricians and Gynecologists, 2003a). It is usually accomplished by occlusion or division of the fallopian tubes to prevent an unfertilized ovum from passing through the fallopian tubes where it can be fertilized by sperm. This can be performed at any time, but at least half of tubal sterilization procedures are done at the time of cesarean or vaginal delivery (MacKay, 2001). Nonpuerperal tubal sterilization is usually accomplished via laparoscope in an outpatient surgical center. Microlaparoscopy is a growing technique that affords the opportunity to perform female sterilization in an office setting, using local analgesia and smaller incisions.

INDICATIONS FOR FEMALE STERILIZATION

The indication for this elective procedure is a request for sterilization with clear understanding that this is a permanent and irreversible procedure. A woman should be counseled regarding alternative choices for contraception (American College of Obstetricians and Gynecologists, 2007).

CONTRAINDICATIONS

Although there are few true contraindications to tubal sterilization other than those pertaining to surgical risks, there are many cautions to be considered before performing the surgery.

CAUTIONS

There will invariably be a number of women who express *regrets about sterilization.* From the CREST study, Jamieson and coworkers (2002) reported that by 5 years, 7 percent of women undergoing tubal ligation had regrets. This is not limited to their own sterilization because 6.1 percent of women whose husbands had undergone vasectomy had similar regrets. The cumulative probability of expressing regret during a subsequent interview within 14 years of tubal sterilization was 20 percent for women aged 30 or younger at sterilization, compared with only 6 percent for those over 30 years (Hillis, 1999). Importantly, 93 percent of women who undergo sterilization have no regrets.

NONPUERPERAL (INTERVAL) TUBAL STERILIZATION

These techniques, including any modifications, basically consist of:

1. Ligation and resection at minilaparotomy, as described earlier for puerperal sterilization (see Section 41-24, Interval Partial Salpingectomy).
2. The application of a variety of permanent rings or clips to the fallopian tubes, usually by laparoscopy (see Section 41-29, Laparoscopic Sterilization).
3. Electrocoagulation of a segment of the oviducts, also usually through a laparoscope (see Section 41-29, Laparoscopic Sterilization).

Surgical Approaches

There are a number of approaches and techniques to perform nonpuerperal tubal sterilization. In developed countries, including the United States, laparoscopic tubal ligation is the leading method used for female sterilization (American College of Obstetricians and

Gynecologists, 2003a). The procedure is frequently done in an ambulatory surgical setting under general anesthesia. The woman can almost always be discharged several hours later. The actual disruption of tubal continuity is accomplished using loops, clips, or electrocoagulation with and without transection of the tube. Because electrocoagulation destroys a large segment of tube, surgical reversal is usually difficult and often not possible.

Minilaparotomy using a 3-cm suprapubic incision is popular, especially in resource-poor countries (Kulier, 2002). The peritoneal cavity can also be entered by colpotomy or culdotomy through the posterior vaginal fornix, although this approach is not commonly used today.

Major morbidity is rare with either laparoscopy or minilaparotomy. In the study by Kulier and associates (2002), minor morbidity was twice as common in the minilaparotomy group.

Methods of Tubal Interruption

A number of techniques or devices can be used to accomplish tubal sterilization via laparoscopy. Details of these have been provided by a number of reviewers. In a Cochrane Review, Nardin and colleagues (2003) concluded that all techniques of interval sterilization are effective in preventing pregnancy. There is not enough evidence to determine which technique is most effective, nor which technique has the most complications because these are uncommon. That said, pregnancy is less likely with an experienced operator, thus the method chosen is usually based on expertise and preferences of the surgeon.

Electrocoagulation is used for destruction of a segment of tube and can be accomplished with either unipolar or bipolar electric current. Although unipolar coagulation has the lowest long-term failure rate, it also has the highest serious complication rate. For this reason, bipolar coagulation rather than unipolar, is favored by most (American College of Obstetricians and Gynecologists, 2003a). When three or more sites are coagulated, the 5-year cumulative probability of pregnancy is about 3 per 1,000 procedures compared with 12 per 1,000 when fewer than three sites are coagulated (Peterson, 1999).

Mechanical methods of tubal occlusion can be accomplished with a silicone rubber band such as the *Falope Ring* and the *Tubal Ring;* the spring-loaded *Hulka-Clemens Clip,* also known as the *Wolf Clip;* or the silicone-lined titanium *Filshie Clip.* Sokal and co-workers (2000) compared the Tubal Ring and Filshie Clip in a randomized trial of 2,746 women and reported similar rates of safety as well as a 1-year pregnancy rate of 1.7 per 1,000 women. All of these methods have a favorable long-term success rate. When done via laparoscopy, these procedures are technically more difficult and they have significantly higher failure rates before experience is gained (Peterson, 2001).

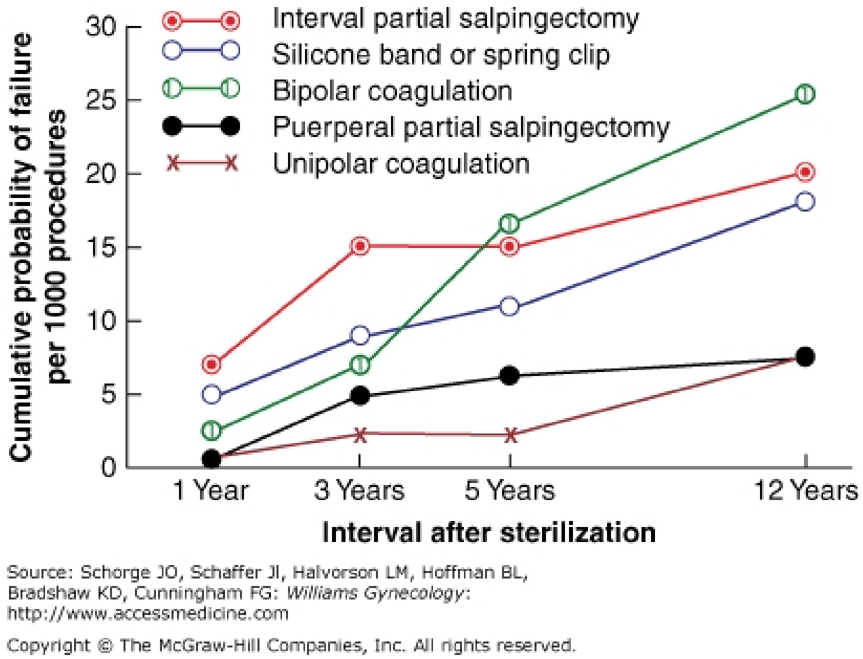
Failure Rates

The reasons for interval tubal failures are not always apparent, but include:

1. Surgical errors, which likely account for 30 to 50 percent of cases.
2. An occlusion-method failure may be due to fistula formation, especially with electrocoagulation procedures. This is less likely now that use of an ammeter is standard. Faulty clips may not be occlusive enough, or the fallopian tube may spontaneously undergo reanastomosis.
3. Equipment failure, such as a defective electric current for the electrocoagulation, may be causative.
4. In some cases, the woman was already pregnant at the time of surgeryâ€”a so-called *luteal phase pregnancy.*

From the CREST studies, 1.3 percent of 10,685 tubal sterilizations were followed by subsequent pregnancy. As shown in Fig. 5-15, some sterilization methods have lower failure rates than others. Even with the same procedure, there are variations in failure rate. For example, when a silicone band was applied solely to the distal portion of at least one fallopian tube, failure rates were higher than if a band was applied to a different portion of the tube (Peterson, 2001).

FIGURE 5-15



Data from the U.S. Collaborative Review of Sterilization (CREST) shows the cumulative probability of pregnancy per 1,000 procedures by five methods of tubal sterilization. *(Data from Peterson, 1996, with permission.)*

The lifetime increased cumulative failure rates over time are supportive that failures after 1 year are not likely due to technical errors. Soderstrom (1985) found that most sterilization failures were not preventable.

Long-Term Complications

In addition to the 15-year cumulative pregnancy rates shown in Figure 5-15, there are other long-term adverse effects as discussed below.

Ectopic Pregnancy

As many as 65 percent of pregnancies that follow a failed electrocoagulation procedure are ectopic, compared with only 10 percent following failure of a ring, clip, or tubal resection method (Hatcher, 1990; Hendrix, 1999; Peterson, 1999). Any symptoms of pregnancy in a woman after tubal sterilization must be investigated, and an ectopic pregnancy must be excluded. Diagnosis and management are discussed in detail in Chapter 7.

Postâ€"Tubal Ligation Syndrome

In 1951, Williams and colleagues described their 22-year experience with long-term evaluation of women who had undergone tubal ligation. They reported an excessive incidence of menorrhagia and intermenstrual bleeding. This later became known as the *postâ€"tubal ligation syndrome.* Subsequently, a similar incidence of menstrual dysfunction was reported in women whose husbands had undergone vasectomy (DeStefano, 1985; Shy, 1992). Since then, debate over the very existence of a unique syndrome has persisted.

Observations from the CREST study are very informative concerning these issues. Peterson and colleagues (2000) compared long-term outcomes of 9,514 women who had undergone tubal sterilization with a cohort of 573 women whose partners had undergone vasectomy. They found that both groups had similar risks for menorrhagia, intermenstrual bleeding, and dysmenorrhea. Women who had undergone sterilization had *decreased* duration and volume of menstrual flow and *less* dysmenorrhea. There was, however, an increased incidence of cycle irregularity in the sterilized women. Harlow and co-workers (2002) reported no significant change in serum levels of FSH, LH, and estradiol in these women. Timonen and co-workers (2002) reported a transient increase in follicular phase serum estradiol levels that normalized by 12 months. Currently, the cause of these findings remains an enigma.

Other Effects

It is controversial whether the incidence of *subsequent hysterectomy* is increased in women who have undergone tubal sterilization (Mall, 2002; Pati, 2000). In a CREST surveillance study, Hillis and associates (1997) reported that 17 percent of women undergoing tubal sterilization had also undergone hysterectomy by 14 years. Although they did not compare this incidence with a cohort control, the indications were similar to those for nonsterilized women undergoing hysterectomy.

Westhoff and Davis (2000) concluded that tubal sterilization likely protects against subsequent *ovarian cancer.* They found no differences in the incidence of subsequent *breast cancer.* According to Holt and colleagues (2003), the incidence of *functional ovarian cysts* is increased almost twofold following tubal sterilization. Levgur and Duvivier (2000) reported that women who had undergone tubal sterilization were highly unlikely to have subsequent *salpingitis* .

Less objective but important psychological sequelae of sterilization have also been evaluated. From the CREST Study, Costello and colleagues (2002) found that tubal ligation did not change *sexual interest or pleasure* in 80 percent of women. The majority of the remaining 20 percent who did report a change, were 10 to 15 times more likely to have *positive effects* .

TUBAL STERILIZATION REVERSAL

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed by either surgery or assisted reproductive techniques. These latter procedures are technically difficult, expensive, and not always successful. Success rates vary greatly depending on the woman's age, the amount of tube remaining, and the technology used. Van Voorhis (2000) reviewed a number of reports and found that pregnancy rates varied from 45 to 90 percent with surgical reversals. For example, pregnancy rates as high as 80 percent have been reported for tubal reanastomosis (Cha, 2001). When neosalpingostomy is done for fimbriectomy reversal, however, successful pregnancies develop in only 30 percent (Tourgeman, 2001). **Almost 10 percent of women undergoing tubal sterilization reversal have an ectopic pregnancy** .

Reversal procedures can be done by laparoscopy or laparotomy, and pregnancy rates are similar with either method (Cha, 2001). In a cost-effectiveness study from Canada, Hawkins and associates (2002) found laparoscopy to have lower costs than laparotomy.

HYSTERECTOMY

For the woman who desires no more children, hysterectomy has many theoretical advantages. In the absence of uterine or other pelvic disease, however, hysterectomy solely for sterilization is difficult to justify.

TRANSCERVICAL STERILIZATION

Sterilization has been performed by using hysteroscopy to visualize the tubal ostia and obliterating them with a variety of compounds or devices.

Intratubal Chemical Methods

Use of a few older methods persists, and a number of new compounds are under investigation (Ballagh, 2003). *Silicone plugs* form after silicone liquid is injected transcervically into the tubes where it hardens. Repeat procedures are needed in 20 percent of women and continued tubal patency is common. Tubal injections with the adhesive *methylcyanoacrylate* cause inflammation, necrosis, and fibrosis. Insertion of *quinacrine pellets* has been used to achieve tubal occlusion in over 100,000 women in other countries. Because of concerns of carcinogenesis from a study of 30,000 Vietnamese women, however, the WHO recommended halting quinacrine usage (Lippes, 2002). Likewise, *erythromycin* placed tubally to incite inflammation has been investigated, but it has an unacceptably high 1-year failure rate of 36 percent (Bairagy, 2004).

Intratubal Devices

In contrast to chemical methods, mechanical devices can be inserted into the proximal fallopian tube using a hysteroscope. Several devices have been evaluated and the *Essure System* (Conceptus, Mountain View, CA) was approved by the FDA in 2002. This device is a microinsert that has a stainless steel inner coil enclosed in polyester fibers and an expandable outer coil of *nitinol* â€”a nickel and titanium alloy used in coronary artery stents (see Section 41-42, Hysteroscopic Placement of Essure Microinserts). The outer coil expands after placement, allowing the fiber to also expand, and as tissue grows within the fiber, tubal occlusion results.

One advantage of the Essure System is that placement can be done as an office hysteroscopy procedure. One major drawback of Essure placement, however, is that a hysterosalpingography must be done at 3 months to assure tubal blockage. Some studies have evaluated the effectiveness of sonography to confirm correct placement (Kerin, 2005; Weston, 2005). Another disadvantage is that the device alone costs almost 1,000 U.S. dollars.

Preliminary results with this and other devices have been encouraging (Association of Reproductive Health Professionals, 2002). Investigators describe use of sedation or paracervical block, or both prior to hysteroscopic placement of Essure microinserts (Cooper, 2003; Mino, 2007). Cooper and associates (2003) reported proper insertion in 464 of 507 women (92 percent). In these women, there had been no pregnancies by 9,620 woman-months. In a similar study, Kerin and colleagues (2001) reported that 97 percent of women expressed very good to excellent satisfaction after 2 years.

Male Sterilization

Nearly a half million men in the United States undergo vasectomy each year (Magnani, 1999). Through a small incision in the scrotum, the lumen of the vas deferens is disrupted to block the passage of sperm from the testes (Fig. 5-16). With local analgesia, the procedure is usually performed within 20 minutes. In their review, Hendrix and colleagues (1999) found that compared with vasectomy, female tubal sterilization has a 20-fold increased complication rate, 10- to 37-fold increased failure rate, and a threefold increased cost. In Dallas in 2006, total charges for a vasectomy were $1,050 compared with almost $5,000 for an outpatient laparoscopic tubal ligation.

FIGURE 5-16

Schematic showing anatomy and procedure for vasectomy.

A disadvantage of vasectomy is that sterility is not immediate. Complete expulsion of sperm stored in the reproductive tract beyond the interrupted vas deferens takes about 3 months or 20 ejaculations (American College of Obstetricians and Gynecologists, 1996). Although most recommend that semen should be analyzed until two consecutive sperm counts are zero, Bradshaw and colleagues (2001) reported that only one azoospermic semen analysis is sufficient. Before azoospermia is documented, another form of

contraception must be used.

The failure rate for vasectomy is much less than 1 percent (Schwingl, 2000). These include failures from unprotected intercourse too soon after ligation, failure to occlude the vas deferens, or recanalization. There is a phenomenon termed *transient sperm reappearance* that usually is not associated with pregnancy. Haldar and co-workers (2000) described temporary low sperm counts in 20 of 2,250 men who had been documented to have azoospermia following vasectomy. Their sperm counts were less than 10,000/mL, and in the 14 retested 1 month later, azoospermia was again confirmed. They concluded that spermatozoa present in the distal vas deferens are slowly released, or that microchannels form with sperm granulomas.

RESTORATION OF FERTILITY

Success after vasectomy reversal depends on several factors. A review of several reports suggests that odds for success are about 50 percent, with somewhat higher rates following microsurgical reanastomosis.

LONG-TERM EFFECTS

Other than regrets, long-term consequences are rare (Amundsen, 2004). After vasectomy, antibodies directed at spermatozoa can frequently be identified. Concern was raised over the possibility that the immune response might cause harmful systemic changes. Despite this, studies have not identified an increase in cardiovascular disease, circulating immune complexes, or damage to retinal blood vessels (Giovannucci, 1992; Goldacre, 1983). Subsequently, Manson and associates (1999) provided data from 1,159 physicians in the U.S. Physicians' Health Study. In a 15-year surveillance, there was no difference in the incidence of myocardial infarction or stroke in men with or without vasectomy. From their review, Schwingl and Guess (2000) also concluded that vasectomy is not followed by accelerated atherogenesis.

There is no convincing evidence of an increased incidence of testicular cancer following vasectomy (Giovannucci, 1992). Earlier studies found no evidence to associate development of *prostatic carcinoma* with vasectomy (Giovannucci, 1993a, 1993b; Hayes, 1993). This changed, however, when Lesko and colleagues (1999) compared surveillance results in 1,216 vasectomized men and 1,400 controls. They reported an almost twofold risk of prostatic cancer in men less than 55 years, but not in older men. Following this, a population-based Danish cohort study found that prostatic cancer was not increased (Lynge, 2002). These findings indicate, at worst, a weak association that may be explicable by greater scrutiny of men who underwent vasectomy (GrÃ¶nberg, 2003).

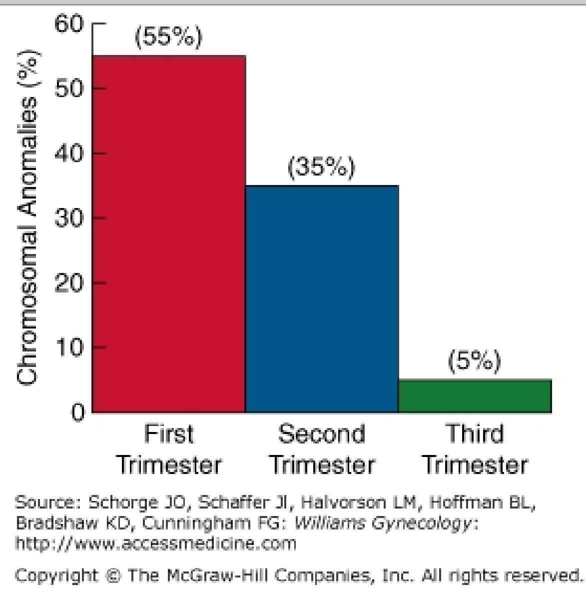
FIRST-TRIMESTER ABORTION: INTRODUCTION

Abortion is the spontaneous or induced termination of pregnancy before fetal viability. Because popular use of the word *abortion* implies a deliberate pregnancy termination, some prefer the word miscarriage to refer to spontaneous fetal loss before viability. Because the widespread use of sonography and serum measurement of human chorionic gonadotropin levels allows identification of an extremely early pregnancy, a number of other names have come into common use. These include, for example, *early pregnancy loss* or *early pregnancy failure* . The National Center for Health Statistics, the Centers for Disease Control and Prevention (CDC), and the World Health Organization (WHO) define *abortion* as pregnancy termination prior to 20 weeks' gestation or a fetus born weighing less than 500 g. Despite this, definitions vary widely according to state laws.

MISCARRIAGE, SPONTANEOUS ABORTION, OR EARLY PREGNANCY FAILURE

More than 80 percent of spontaneous abortions are in the first 12 weeks of pregnancy. As shown in Fig. 6-1, at least half result from chromosomal anomalies. There also appears to be a 1.5 male:female gender ratio in early abortuses (Benirschke, 2000). After the first trimester, both the abortion rate and the incidence of associated chromosomal anomalies decrease.

FIGURE 6-1



Frequency of chromosomal anomalies in abortuses and stillbirths during each trimester. Approximate percentages for each group are shown. *(Data from Eiben, 1990, Fantel, 1980, and Warburton, 1980, with permission.)*

Hemorrhage into the decidua basalis, followed by necrosis of tissues adjacent to the bleeding, usually accompanies early miscarriage. In these cases, the ovum detaches, stimulating uterine contractions that result in its expulsion. When a gestational sac is opened, fluid is commonly found surrounding a small macerated fetus, or alternatively no fetus is visibleâ€"the so-called *blighted ovum* .

Incidence

In a meticulous investigation of 221 healthy women studied through 707 menstrual cycles, Wilcox and colleagues (1988) reported that 31 percent of pregnancies are lost after implantation. They used highly specific assays for minute concentrations of β-human chorionic gonadotropin (β-hCG) and reported that two thirds of these early loses were *clinically silent* .

A number of factors influence the spontaneous abortion rate, and it is not known if those that are clinically silent are affected. For example, clinically apparent miscarriage increases with parity as well as with maternal and paternal age (Gracia, 2005; Warburton, 1964; Wilson, 1986). The frequency doubles from 12 percent in women younger than 20 years to 26 percent in those older than 40. For the same comparison of paternal ages, the frequency increases from 12 to 20 percent. Again, it is not known if clinically silent miscarriages are similarly affected by these factors.

Although mechanisms responsible for abortion are not always apparent, during the first 3 months of pregnancy, death of the embryo or fetus nearly always precedes spontaneous expulsion. Thus, finding the cause of early abortion involves ascertaining the cause of fetal death. In later losses, the fetus usually does not die before expulsion and other explanations are sought.

Fetal Factors

Early spontaneous abortions commonly display a developmental abnormality of the zygote, embryo, early fetus, or at times the placenta. Of 1,000 spontaneous abortions analyzed by Hertig and Sheldon (1943), one-half had a degenerated or absent embryo, which are the blighted ova described previously. In 50 to 60 percent of spontaneously aborted embryos and early fetuses, abnormalities in chromosomal numbers account for most wastage (Table 6-1).

ANEUPLOID ABORTION

About 95 percent of chromosomal abnormalities are caused by maternal gametogenesis errors, 5 percent are due to paternal errors (Jacobs, 1980). Those found most commonly in abortuses are listed in Table 6-1.

Autosomal trisomy is the most frequently identified chromosomal anomaly with first-trimester miscarriages. Although most trisomies result from *isolated nondisjunction* , balanced structural chromosomal rearrangements are present in one partner in 2 to 4 percent of couples with recurrent miscarriage (American College of Obstetricians and Gynecologists, 2001). Autosomal trisomies for all except chromosome number 1 have been identified in abortuses, and those with autosomes 13, 16, 18, 21, and 22 are most common. Bianco and colleagues (2006) recently described that a previous miscarriage increased the risk of a subsequent fetal aneuploidy to 1.67 percent from a baseline risk of 1.39 percent in almost 47,000 women. Two or three previous miscarriages

increased this to 1.84 and 2.18 percent, respectively.

Monosomy X (45, X), is the single most common specific chromosomal abnormality. These cause Turner syndrome, which usually results in abortion and much less frequently in live-born females (see Chap. 16, Abnormal Karyotype). Conversely, *autosomal monosomy* is rare and incompatible with life.

Triploidy is often associated with hydropic placental (molar) degeneration (see Chap. 37, Clinical Findings). Incomplete (partial) hydatidiform moles may be triploid or trisomic for only chromosome 16. Although these fetuses frequently abort early, the few carried longer are grossly malformed. Advanced maternal and paternal age does not increase the incidence of triploidy.

Tetraploid abortuses are rarely live born and are most often aborted early in gestation.

Chromosomal structural abnormalities infrequently cause abortion. Some infants who are live born with a balanced translocation may appear normal as discussed in Parental Chromosomal Abnormalities.

EUPLOID ABORTION

Chromosomally normal fetuses tend to abort later in gestation than those with aneuploidy. For example, although 75 percent of aneuploid abortions occurred before 8 weeks, euploid abortions peaked at about 13 weeks (Kajii, 1980). The incidence of euploid abortions increases dramatically after maternal age exceeds 35 years (Stein, 1980).

Maternal Factors

The causes of euploid abortions are poorly understood, although a variety of medical disorders, environmental conditions, and developmental abnormalities have been implicated. The well-known influence of maternal age was discussed above.

INFECTIONS

According to the American College of Obstetricians and Gynecologists (2001), infections are an uncommon cause of early abortion. Even in their study of insulin-dependent diabetic womenâ€”presumably more susceptible to infectionâ€”Simpson and co-workers (1996) found no evidence of infection-induced miscarriage.

A number of specific infections have been studied. For example, although *Brucella abortus* and *Campylobacter fetus* cause abortion in cattle, they do not do so in humans (Sauerwein, 1993). There is also no evidence that either *Listeria monocytogenes* or *Chlamydia trachomatis* stimulate abortions in humans (Feist, 1999; Osser, 1996; Paukku, 1999). In a prospective study, infection with herpes simplex virus in early pregnancy also did not increase the incidence (Brown, 1997). Evidence that *Toxoplasma gondii* causes abortion in humans remains inconclusive.

Data concerning a link between some other infections and increased abortion are conflicting. For example, Quinn and co-workers (1983a, b) provided serologic evidence that supports a role for *Mycoplasma hominis* and *Ureaplasma urealyticum* . Conversely, Temmerman and associates (1992) found no link between genital mycoplasma and spontaneous abortion. They did find abortion to be independently associated with serologic evidence of syphilis and human immunodeficiency virus (HIV)-1 infection, and with vaginal colonization with group B streptococci. In contrast, van Benthem and associates (2000) reported that women had the same risk for spontaneous abortion before and after they had developed HIV infection. Oakeshott and associates (2002) reported an association between second, but not first-trimester miscarriage, and bacterial vaginosis.

CHRONIC DEBILITATING DISEASES

Early abortions are rarely secondary to chronic wasting diseases such as tuberculosis or carcinomatosis. Celiac sprue, however, has been reported to cause both male and female infertility and recurrent abortions (Sher, 1994).

ENDOCRINE ABNORMALITIES

Hypothyroidism

Iodine deficiency may be associated with miscarriages (CastaÃ±eda, 2002). Thyroid hormone deficiency is common in women, and it is usually caused by an autoimmune disorder, but any effects of hypothyroidism on early pregnancy loss have not been adequately studied. Even without hypothyroidism, thyroid autoantibodies are associated with an increased incidence of miscarriage

(Abramson, 2001; Lakasing, 2005). As discussed in Hypothyroidism, the data are less convincing that women with recurrent miscarriage have a greater incidence of antithyroid antibodies than normal controls.

Diabetes Mellitus

Spontaneous abortion and major congenital malformation rates are both increased in women with insulin-dependent diabetes (Greene, 1999). The risk appears related to the degree of metabolic control in early pregnancy. In a prospective study, Mills and associates (1988) reported that excellent glucose control within 21 days of conception resulted in a miscarriage rate similar to that in nondiabetic controls. Poor glucose control, however, resulted in a markedly increased abortion rate. Overt diabetes is a cause of recurrent pregnancy loss, and Craig and co-workers (2002) have reported a higher incidence of insulin resistance in those with recurrent miscarriage. This is discussed further in Diabetes Mellitus.

NUTRITION

Dietary deficiency of any one nutrient or moderate deficiency of all nutrients does not appear to be an important cause of abortion. Even hyperemesis gravidarum during early pregnancy with significant weight loss is rarely followed by miscarriage.

DRUG USE AND ENVIRONMENTAL FACTORS

A variety of different agents have been reported to be associated with an increased incidence of abortion.

Tobacco

Smoking has been linked with an increased risk for euploid abortion (Kline, 1980). Two studies suggested that the abortion risk increases in a linear fashion with the number of cigarettes smoked per day (Armstrong, 1992; Chatenoud, 1998). Two subsequent studies, however, failed to support this association (Rasch, 2003; Wisborg, 2003).

Alcohol

Both spontaneous abortion and fetal anomalies may result from frequent alcohol use during the first 8 weeks of pregnancy (Floyd, 1999). The risk seems to be related to both frequency and dose (Armstrong, 1992; Kline, 1980). A low level of alcohol consumption during pregnancy was not associated with a significant risk for abortion (Cavallo, 1995; Kesmodel, 2002).

Caffeine

Armstrong and associates (1992) reported that women who consumed at least five cups of coffee per day had a slightly increased abortion risk, and that above this threshold, the risk correlated linearly. Similarly, Cnattingius and colleagues (2000) observed a significantly increased abortion risk only in women who consumed at least 500 mg of caffeine dailyâ€”roughly equivalent to 5 cups of coffee. Klebanoff and associates (1999) reported that pregnant women in whom levels of the caffeine metabolite, paraxanthine, were extremely elevated had a twofold risk for miscarriage. They concluded that moderate caffeine consumption was unlikely to cause spontaneous abortion.

Radiation

In therapeutic doses given to treat malignancy, radiation is certainly an abortifacient. Although lower doses are less toxic, the human dose to effect abortion is not precisely known. According to Brent (1999), exposure to less than 5 rads does not increase the risk for miscarriage.

Contraceptives

Oral contraceptives or spermicidal agents used in contraceptive creams and jellies are not associated with an increased miscarriage rate. When intrauterine devices fail to prevent pregnancy, however, the risk of abortion, and specifically septic abortion, increases substantively (see Chap. 5, Pregnancy with Retained IUD).

Environmental Toxins

Accurately assessing the relationship between environmental exposures and miscarriage poses challenges. There may be difficulties in measuring the intensity and duration of exposure, and there is little information to conclusively indict or absolve any specific agent. Nevertheless, it seems prudent to limit exposure of pregnant women to environmental toxins.

Some studies include those by Barlow and Sullivan (1982) who found that arsenic, lead, formaldehyde, benzene, and ethylene oxide possibly cause miscarriages. Video display terminals and exposure to their accompanying electromagnetic fields do not adversely affect miscarriage rates (Schnorr, 1991). Similarly, no effects were found with occupational exposure to ultrasound (Taskinen, 1990). An increased risk of miscarriage has been described for dental assistants exposed to 3 or more hours of nitrous oxide per day in offices without gas-scavenging equipment, but not in offices using such equipment (Rowland, 1995). Before the use of such equipment, Boivin (1997) concluded that women occupationally exposed to anesthetic gases had an increased risk for miscarriage. In another meta-analysis, Dranitsaris and colleagues (2005) identified a small incremental risk for spontaneous abortion in female staff who worked with cytoxic chemotherapeutic drugs.

IMMUNOLOGIC FACTORS

A number of immune-mediated disorders are associated with early pregnancy loss. Many tend to be repetitive, and they are considered with recurrent miscarriage (Immunologic Factors).

INHERITED THROMBOPHILIAS

There are a number of genetic disorders of blood coagulation that may increase the risk of both arterial and venous thrombosis. Some of the better studied thrombophilias are caused by mutations of the gene for factor V Leiden, prothrombin, antithrombin, proteins C and S, and methylene tetrahydrofolate reductase (hyperhomocysteinemia). Because these are most commonly associated with recurrent miscarriage, they are considered in detail in Inherited Thrombophilias.

MATERNAL SURGERY

Uncomplicated abdominal or pelvic surgery performed during early pregnancy does not appear to increase the risk for abortion. Ovarian tumors are generally removed without interfering with pregnancy. An important exception involves early removal of the corpus luteum cyst or the ovary in which the corpus luteum resides. If performed prior to 10 weeks' gestation, supplemental progesterone is indicated. If between 8 and 10 weeks, then only one injection of intramuscular 17-hydroxyprogesterone caproate, 150 mg, is required immediately after surgery. If the corpus luteum is excised between 6 and 8 weeks, then two additional doses should be given 1 and 2 weeks after the first.

TRAUMA

Presumably, major abdominal trauma can precipitate abortion, however, this is unusual in early pregnancy. Any effects of minor trauma on abortion rates is difficult to ascertain. Minor trauma without pregnancy complication is often forgotten, whereas minor trauma temporally associated with miscarriage is more likely to be recalled. In general, trauma contributes minimally to the incidence of abortion.

UTERINE DEFECTS

Acquired Uterine Defects

Large and multiple uterine leiomyomas are common, and they may cause miscarriage. In most instances, their location is more important than their size (see Chap. 9, Infertility and Pregnancy Wastage). Uterine synechiaeâ€"known as *Asherman syndrome* â€"usually result from destruction of large areas of endometrium by curettage. A hysterosalpingogram may show characteristic multiple filling defects, but hysteroscopy is more accurate (Figs. 19-5, and 41-41.1) (Raziel, 1994). With subsequent pregnancy, the amount of remaining endometrium may be insufficient to support the pregnancy, and abortion may ensue. Treatment is discussed in Chapter 20, Intrauterine Adhesions.

Developmental Uterine Defects

Abnormal mÃ¼llerian duct formation or fusion defects may develop spontaneously or may follow in utero exposure to diethylstilbestrol (see Chap. 18, Diethylstilbestrol-Induced Reproductive Tract Abnormalities). Although they can cause midpregnancy loss and other preterm birth and pregnancy complications, it is controversial whether uterine defects cause early miscarriage. As discussed in Anatomic Factors, corrective procedures to prevent abortion, if done at all, should be performed as a last resort, with a full understanding that they may lack efficacy (American College of Obstetricians and Gynecologists, 2001).

Incompetent Cervix

This describes a discrete obstetric entity characterized by painless cervical dilatation in the second trimester. It can be followed by prolapse and ballooning of membranes into the vagina, and ultimately expulsion of an immature fetus. Chasen and associates (2005) reported that a prior dilatation and evacuation (D&E) or dilatation and extraction (D&X) after 20 weeks does not increase the chances of an incompetent cervix. This condition is discussed in detail in Chapter 9 of *Williams Obstetrics* (Cunningham, 2005).

Paternal Factors

Little is known about paternal factors in the genesis of miscarriage. Certainly, chromosomal abnormalities in sperm have been associated with abortion (Carrell, 2003).

Clinical Classification of Spontaneous Abortion

The clinical aspects of spontaneous abortion can be classified a number of ways. Commonly used subgroups include threatened, inevitable, incomplete, and missed abortion. If the products of conception and pelvic organs are infected, septic abortion is diagnosed. Finally, recurrent miscarriageâ€"also termed recurrent pregnancy lossâ€"describes consecutive early losses with implied similar etiology.

THREATENED ABORTION

The clinical diagnosis of threatened abortion is presumed when a bloody vaginal discharge or bleeding appears through a closed cervical os during the first half of pregnancy. Vaginal spotting or heavier bleeding develops in 20 to 25 percent of women during early gestation and it may persist for days or weeks. Approximately half of these pregnancies will abort, although the risk is substantially lower if fetal cardiac activity can be documented (Tongsong, 1995). Eddleman and associates (2006) designed an individualized risk assessment model for spontaneous pregnancy loss in over 35,000 pregnancies. By far, bleeding during the current pregnancy was the most predictive risk factor for pregnancy loss. Even if abortion does not follow early bleeding, these fetuses are at increased risk for preterm delivery, low birthweight, and perinatal death (Johns, 2006; Weiss, 2002). Fortunately, the risk of a malformed surviving infant does not appear to be increased. There are also maternal risks that include antepartum hemorrhage, manual removal of the placenta, and cesarean delivery (Wijesiriwardana, 2006).

Some bleeding near the time of expected menses may be physiologic. Cervical lesions commonly bleed in early pregnancy, especially after intercourse. Polyps presenting at the external cervical os and decidual reaction in the cervix also tend to bleed in early gestation. Bleeding from these benign sources is not accompanied by lower abdominal pain and low backache.

With miscarriage, bleeding usually begins first, and cramping abdominal pain follows a few hours to several days later. The pain may present variablyâ€"as anterior and clearly rhythmic cramps; as a persistent low backache, associated with a feeling of pelvic pressure; or as a dull, midline, suprapubic discomfort. Whichever form the pain takes, the combination of bleeding and pain predicts a poor prognosis for pregnancy continuation.

Because ectopic pregnancy, ovarian torsion, and the other types of abortion may mimic threatened abortion, the threshold to examine women with vaginal bleeding and pain should be low. If bleeding is persistent or heavy, a hematocrit should be performed. If blood loss is sufficient to cause significant anemia or hypovolemia, pregnancy evacuation is usually indicated.

There are no effective therapies for threatened abortion. Bedrest, although often prescribed, does not alter its course. Acetaminophen-based analgesia may be given to help relieve discomfort. As discussed in Chapter 7, Differential Diagnosis, transvaginal sonography, serial serum quantitative β-hCG and serum progesterone levels, used alone or in combination, can help to ascertain if a fetus is alive and within the uterus. None of these tests in early gestation are 100-percent accurate to confirm fetal death, thus subsequent evaluations over a week or two may be necessary. **Ectopic pregnancy should always be considered in the differential diagnosis of threatened abortion** . In one report, Condous and colleagues (2005) described 152 women with heavy bleeding who were diagnosed to have a completed miscarriage and an endometrial thickness <15 mm. Almost 6 percent of these women were found to have an ectopic pregnancy on further evaluation.

It is imperative to recognize an early ectopic pregnancy before tubal rupture develops. For women with abnormal bleeding or pelvic pain who have low levels of β-hCG detectable in serum, attempts are made to differentiate an extrauterine pregnancy from a normal uterine pregnancy or an early miscarriage. Barnhart and colleagues (2004a) have provided data concerning composite

serum β-hCG disappearance curves in women with early miscarriage (Fig. 6-2). This same group has provided similar data for symptomatic women with early pregnancies who go on to have a normal pregnancy (Barnhart, 2004b).

The light dotted lines represent actual curves from subjects. The solid line is the predicted curve based on the summary of all data. The two hatched dark lines represent the 95-percent confidence interval of the predicted curve. *(From Barnhart, 2004a, with permission.)*

ANTI-D IMMUNOGLOBULIN

Treatment of D-negative women with anti-D immunoglobulin is recommended following miscarriage because up to 5 percent of D-negative women will become isoimmunized without it. This practice is controversial with threatened abortion because it lacks evidence-based support (American College of Obstetricians and Gynecologists, 1999; Weissman, 2002).

INEVITABLE ABORTION

Gross rupture of the membranes, evidenced by leaking amnionic fluid, in the presence of cervical dilatation signals almost certain abortion. Commonly, either uterine contractions begin promptly, resulting in miscarriage, or infection develops. Rarely, a gush of fluid from the uterus during the first half of pregnancy is without serious consequence. The fluid may have collected previously between the amnion and chorion. Because of this possibility, if a sudden discharge of fluid in early pregnancy occurs before pain, fever, or bleeding, then diminished activity with observation is reasonable. If after 48 hours no additional amnionic fluid has escaped and if there is no bleeding, pain, or fever, a woman may resume her usual activities except for any form of vaginal penetration. If, however, the gush of fluid is accompanied or followed by bleeding, pain, or fever, then abortion should be considered inevitable, and the uterus emptied.

INCOMPLETE ABORTION

Bleeding ensues when the placenta, in whole or in part, detaches from the uterus. During incomplete abortion, the internal cervical os opens and allows passage of blood. The fetus and placenta may remain entirely in utero or may partially extrude through the

dilated os. Before 10 weeks, the fetus and placenta are commonly expelled together, but later they are delivered separately. In some women, additional cervical dilatation is necessary before curettage is performed. In many cases, retained placental tissue simply lies loosely in the cervical canal, allowing easy extraction from an exposed external os with ring forceps. Suction curettage, as described later, effectively evacuates the uterus. In clinically stable women, expectant management can also be a reasonable option (Blohm, 2005).

Hemorrhage from incomplete abortion of a more advanced pregnancy is occasionally severe but rarely fatal. Therefore, in women with more advanced pregnancies or with heavy bleeding, evacuation is promptly performed. If there is fever, appropriate antibiotics are given before curettage.

MISSED ABORTIONÂ€”EARLY PREGNANCY FAILURE

The term *missed abortion* is contemporaneously imprecise because it was defined many decades before the advent of immunologic pregnancy tests and sonography (Fig. 6-3). It was used to describe dead products of conception that were retained for days, weeks, or even months in the uterus with a closed cervical os. Because spontaneous miscarriages are almost always preceded by embryofetal death, most were correctly referred to as "missed". In the typical instance, early pregnancy appears to be normal. Characteristically, amenorrhea, nausea and vomiting, breast changes, and uterine growth are present. After embryonic death, there may or may not be vaginal bleeding or other symptoms of threatened abortion.

FIGURE 6-3

Because technology now allows identification of fetal or embryonic death at this early stage, most women choose medical or surgical termination at the time of discovery. If the pregnancy is not terminated, and if miscarriage does not follow for days or weeks, then uterine size remains unchanged, and then gradually becomes smaller. Mammary changes usually regress, and women often lose a few pounds. Many women have no symptoms during this period except persistent amenorrhea. If the missed abortion terminates spontaneously, and most do, the process of expulsion is the same as in any abortion.

SEPTIC ABORTION

In the past septic abortion and maternal deaths associated with criminal abortions were common, but currently are rare. That said, miscarriage and elective abortion are occasionally complicated by severe and even fatal infections (Barrett, 2002). Uterine infection is the most common manifestation of postabortal sepsis, but parametritis, peritonitis, septicemia, and even endocarditis, occasionally develop (Vartian, 1991). Treatment of infection includes prompt administration of intravenous broad-spectrum antibiotics followed by uterine evacuation (see Chap. 3, Treatment). With severe sepsis syndrome, acute respiratory distress syndrome or disseminated intravascular coagulopathy may develop, and supportive care is essential.

In mid-2005, the Centers for Disease Control and Prevention (2005) reported four deaths associated with medical abortion that were caused by toxic shock syndrome and *Clostridium sordellii* infection. Fischer and colleagues (2005) detailed these infections and described clinical manifestations that began within 1 week after the medically induced abortion. The hallmark was severe endothelial injury with capillary leakage and hemoconcentration, hypotension, and profound leukocytosis. As emphasized by Greene (2005), these infections are rare events but bear close surveillance.

Management

With death of the conceptus now easy to verify with current sonographic technology, management can be more individualized. Expectant, medical, and surgical management are all reasonable options unless there is serious bleeding or infection. Surgical treatment is definitive and predictable, but is invasive and not necessary for all women. Expectant and medical management may obviate curettage, but are associated with unpredictable bleeding, and some women will need unscheduled surgery. For example, in the observational study of Luise and colleagues (2002), 81 percent of almost 1,100 women with suspected first-trimester miscarriage reported spontaneous resolution.

A number of randomized studies have been done to evaluate these methods. In many cases, however, the studies themselves are not comparable because different criteria were used for inclusion, and various techniques were employed. For example, if there is vaginal bleeding, then medical therapy for early pregnancy failure is enhanced (Creinin, 2006). Some of these studies are listed in Table 6-2. A number of generalizations can be made:

1. Success is dependent on the type of early pregnancy failure.
2. With spontaneous incomplete abortion, expectant management results in spontaneous completion in about 80 percent of cases. It is likely that treatment with prostaglandin E_1 (PGE_1) increases this rate only slightly.
3. For early pregnancy failure, otherwise not further defined, PGE_1 given orally or vaginally is effective for completed abortion by 7 days in about 85 percent.
4. Curettage is a quick resolution that is almost 100 percent successful in completing early pregnancy failures.

Table 6-2 Randomized Controlled Studies for Management of Early Pregnancy Loss

SAB = spontaneous abortion; PGE = prostaglandin E.

[a] Includes anembryonic gestation, embryonic or fetal death, without signs of incomplete SAB.

[b] Includes anembryonic gestation, embryonic or fetal death, or incomplete or inevitable SAB.

Thus, there are several management options that can be selected by the woman and her gynecologist. Of course, with dangerous hemorrhage or infection, prompt completion of abortionâ€"either medically or surgicallyâ€"is warranted.

RECURRENT PREGNANCY LOSS

Also known as *recurrent spontaneous abortion* and *recurrent pregnancy loss* , recurrent miscarriage is classically defined as three or more consecutive pregnancy losses at 20 weeks' gestation or less or with fetal weights less than 500 g. Most women with recurrent miscarriage have embryonic or early fetal loss, with recurrent losses after 14 weeks being much less common (Stephenson, 2007). Although the formal definition includes three or more miscarriages, many agree that an evaluation should be performed, or at least considered, following two consecutive losses. This is because the risk of subsequent loss after two successive miscarriages is similar to that following three lossesâ€"approximately 30 percent (Harger, 1983). Remarkably, as shown in Table 6-3, the chance of successful pregnancy may approach 50 percent even after six losses (Poland, 1977; Warburton, 1964).

Recurrent miscarriage should be distinguished from sporadic pregnancy loss described in the previous section. Sporadic loss implies that intervening pregnancies have resulted in healthy infants. Others distinguish *primary recurrent miscarriage* â€"no successful pregnanciesâ€"from *secondary recurrent miscarriage* â€"one prior live birth. The latter group does not reach a risk of subsequent loss of 32 percent until after three miscarriages. Thus, it is reasonable to delay evaluation of secondary recurrent pregnancy loss until there have been three losses (Poland, 1977).

The causes of recurrent miscarriage parallel those of sporadic miscarriage, although the relative incidence differs between the two categories (Reddy, 2007). For example, first-trimester losses with recurrent miscarriage have a significantly lower incidence of genetic anomalies (Sullivan, 2004). In one series, normal karyotypes were identified in half of recurrent miscarriages but only a fourth of sporadic losses. The timing of the pregnancy losses may provide a clue to their cause. By way of another example, genetic factors most frequently result in early embryonic losses, whereas autoimmune or anatomic abnormalities are more likely to result in second-trimester losses (Schust, 2002).

Parental Chromosomal Abnormalities

Although these account for only 2 to 4 percent of recurrent losses, karyotypic evaluation of both parents remains a critical part of evaluation. Therapel and colleagues (1985) summarized data from 79 studies of couples with two or more miscarriages. These included 8208 women and 7834 men, and chromosomal abnormalities were detected in 2.9 percentâ€"a fivefold greater incidence than that observed in the general population. The male: female gender ratio of abnormalities was about 2:1. Balanced reciprocal translocations accounted for 50 percent of identified abnormalities; Robertsonian translocations for 24 percent; X chromosome mosaicism such as 47, XXY for 12 percent; and inversions and a variety of other anomalies comprised the remainder.

If one parent carries a balanced translocation, the karyotype of the resultant pregnancy may be normal, the same balanced translocation, or an unbalanced translocation (Fig. 6-4). Balanced translocations are likely to cause subsequent recurrent miscarriage in the offspring. An unbalanced translocation may produce either a miscarriage, fetal anomaly, or stillborn.

FIGURE 6-4

Gametes produced by a balanced translocation carrier.

The prognosis for these couples, however, is good. Franssen and colleagues (2006) studied 247 couples with a balanced translocation and reported that although they had an increased miscarriage rate compared with noncarriers, almost 85 percent had at least one healthy infant. Thus, a history of second- trimester loss or fetal anomaly should raise the suspicion that an abnormal chromosome pattern is present in one parent. All couples with an abnormal karyotype should be offered preimplantation genetic counseling.

Some recommend that fetal tissue be routinely studied for chromosomal analysis following a second consecutive miscarriage (Stephenson, 2006). One reason cited is that an abnormal karyotype suggests a sporadic loss, and therefore does not predict increased risk for the next pregnancy. Conversely, an abortus with a normal karyotype might suggest an alternative cause for the pregnancy loss and imply the need for earlier evaluation.

Opponents of routine analysis cite the extreme expense. They note that it should be presumed that a woman with recurrent miscarriages has the same risk of an aneuploid abortion as any other womanâ€”about 50 percent (see Table 6-1). Moreover, karyotyping of products of conception may actually be misleading. In many cases, cells cannot be grown in culture because of embryonic tissue death. As a general rule, tissue obtained by curettage is more likely to grow in culture. Also, detection of a 46, XX karyotype may simply reflect contamination with maternal tissues. And many conceptions are chromosomal mosaics of which a significant proportion will develop into phenotypically and functionally normal neonates. This is particularly true if the abnormal cells are from *placental mosaicism* . Finally, karyotypically normal cells are likely to have a growth advantage in culture.

For all of these reasons, karyotyping of products of conception may not accurately reflect fetal karyotype. Because of the expense

and limited information provided, we do not recommend routine karyotyping of pregnancy products.

Anatomic Factors

A number of anatomic abnormalities of the genital tract have been implicated in recurrent miscarriage. According to Devi Wold and colleagues (2006), 15 percent of women with three or more consecutive miscarriages have a congenital or acquired uterine anomaly. These essentially are the same as those associated with all miscarriages and are discussed in Developmental Uterine Defects. They include acquired uterine abnormalities such as intrauterine synechiaeâ€"Asherman syndrome, leiomyoma, endometrial polyp, and cervical incompetence. Developmental defects include septate, bicornuate, and unicornuate uterus, as well as uterine didelphys. Also, reproductive-tract abnormalities may be associated with in utero exposure to diethylstilbestrol and include a small uterine cavity and incompetent cervix. The frequency of these anomalies in women with recurrent miscarriage varies widely depending on testing used and criteria set for abnormality.

Salim and colleagues (2003) described nearly 2,500 women who were screened for developmental uterine anomalies using three-dimensional sonography. Anomalies were identified in 24 percent of women with recurrent miscarriage, but only 5 percent of normal controls without recurrent miscarriage. In other studies, the prevalence of uterine anomalies has been estimated to be only 7 to 15 percent in women with repetitive losses (Ashton, 1988; Makino, 1992).

TREATMENT

As discussed in Developmental Uterine Defects, the evidence is not robust to link these anatomic anomalies with early pregnancy loss. It is therefore difficult to prove that their correction improves pregnancy outcome (American College of Obstetricians and Gynecologists, 2001). That said, Saygili-Yilmaz and colleagues (2003) retrospectively reviewed pregnancy outcomes following hysteroscopic metroplasty in women who had a septate uterus and more than two prior miscarriages. In 59 such women, the incidence of miscarriage decreased from 96 to 10 percent following surgery, and term pregnancies increased from none to 70 percent. In another study, Saygili-Yilmaz and associates (2002) reported that the miscarriage rate of 65 percent with a septum decreased to 15 percent after hysteroscopic resection. A further discussion of treatment outcome is found in Chapter 18, Diagnosis and Treatment.

In another retrospective review, Katz and colleagues evaluated 90 women with uterine synechiae who had at least two prior miscarriages or preterm perinatal deaths or both. With adhesiolysis, miscarriage rates decreased from 79 to 22 percent and term pregnancies increased from 18 to 69 percent. Other studies have reported similar outcomes with prognosis correlating to the severity of the disease (Al-Inany, 2001; Goldenberg, 1995; Katz, 1996). Directed hysteroscopic lysis of adhesions is preferable to curettage (see Section 41-41, Lysis of Intrauterine Adhesions).

As described in Chapter 9, Infertility and Pregnancy Wastage, it is controversial whether submucous myomas cause recurrent miscarriage more than infrequently. If symptomatic, most agree that submucosal and intracavitary fibroids should be excised. In recent studies of women undergoing in vitro fertilization, pregnancy outcomes were adversely affected by submucosal myomas, but not by those that were subserosal or intramural and less than 5 to 7 cm (Jun, 2001; Ramzy, 1998).

Immunologic Factors

Much attention has focused on the immune system as important in recurrent pregnancy loss. In their analysis of published studies, Yetman and Kutteh (1996) determined that 15 percent of more than 1,000 women with recurrent miscarriage had recognized autoimmune factors. Two primary pathophysiologic models are the *autoimmune theory* , immunity against self, and the *alloimmune theory* , immunity against another person.

AUTOIMMUNE FACTORS

Miscarriages are more common in women with systemic lupus erythematosus (Warren, 2004). Many of these women have antiphospholipid antibodies, which are a family of autoantibodies that bind to negatively charged phospholipids, phospholipid-binding proteins, or a combination of the two (Branch, 2003). They also are found in women without lupus. Indeed, in up to 5 percent of normal pregnant women, lupus anticoagulant (LAC) and anticardiolipin antibody (ACA) have been linked with excessive pregnancy wastage. Instead of causing miscarriage, they more likely are found with fetal death after midpregnancy. Because of this, fetal death is one criterion for diagnosis of the *antiphospholipid syndrome* (Lakasing, 2005).

Antiphospholipid Antibody Syndrome

Diagnosis of this syndrome requires at least one of each clinical and laboratory criterion (American College of Obstetricians and Gynecologists, 2005a). These are listed in Table 6-4. Screening tests for lupus anticoagulant vary by institution, but include a number of suitable tests.

Table 6-4 Clinical and Laboratory Criteria for Diagnosis of Antiphospholipid Antibody Syndrome[a]

Clinical criteria 1. Three or more consecutive spontaneous abortions before 10 weeks (recurrent pregnancy loss); delivery before 34 weeks; one or more unexplained fetal deaths of a morphologically normal infant; or severe preeclampsia or placental insufficiency necessitating delivery before 34 weeks. 2. Arterial or vascular thrombosis without an obvious precipitating cause; small-vessel thrombosis in any tissue or organ, without significant evidence of vasculitis.
Laboratory criteria 1. Moderate to high levels of IgG or IgM anticardiolipin antibodies. 2. Detection of lupus anticoagulant. These tests must be positive on at least two occasions at least 6 weeks apart.

IgG = immunoglobulin G; IgM = immunoglobulin M.

[a] At least one clinical and laboratory criterion each must be present for diagnosis.

Antiphospholipid antibodies are the only autoimmune condition that can be correlated with adverse pregnancy outcome. They have been proposed to cause fetal loss because these antibodies inhibit release of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation. In contrast, platelets produce thromboxane A_2 which is a vasoconstrictor that also promotes platelet aggregation. These autoantibodies have also been shown to inhibit protein C activation, which results in coagulation and fibrin C formation. Clinically, these events that lead to hypercoagulability and recurrent thrombosis within the placenta.

Women with both a history of early fetal loss and high levels of these antibodies may have a 70 percent miscarriage recurrence (Dudley and Branch, 1991). In a prospective study of 860 women screened for anticardiolipin antibody in the first trimester, Yasuda and colleagues (1995) reported that 7 percent tested positive. Miscarriage developed in 25 percent of the antibody-positive group, compared with only 10 percent of the negative group. In another study, however, Simpson and associates (1998) found no association between early pregnancy loss and the presence of either anticardiolipin antibody or lupus anticoagulant.

Treatment

There are treatment regimens for antiphospholipid syndrome that increase live birth rates. Two randomized trials support that treatment with a combination of heparin plus low-dose aspirin can improve the live birth rate compared with low-dose aspirin alone. Kutteh (1996) randomized 50 such women to receive either low-dose aspirin alone or low-dose aspirin plus heparin. Women who received both aspirin and heparin had significantly more viable infantsâ€”80 versus 44 percent, respectively. Rai and colleagues (1997) reported a 77-percent live birth rate with low-dose aspirin plus low-dose heparin therapyâ€”5000 units twice dailyâ€"versus 42 percent with aspirin alone. In contrast, Farquharson and associates (2002) observed a 72-percent live birth rate using low-dose aspirin alone versus a 78-percent rate using low-dose aspirin plus low-dose low-molecular-weight heparin.

As emphasized by Branch and Khamashta (2003), the discrepant reports are confusing, and therapeutic guidelines are blurred. Because of this, we individualize therapy for women who meet the criteria for antiphospholipid syndrome and involve them in the decision-making process. We recommend a regimen proposed by the American College of Obstetricians and Gynecologists (2005a). We give low-dose aspirinâ€"81 mg orally per day, along with unfractionated heparinâ€"5,000 units subcutaneously, twice daily. This therapy, begun when pregnancy is diagnosed, is continued until delivery. Although this treatment may improve overall pregnancy success, these women remain at high risk for preterm labor, premature rupture of membranes, fetal growth restriction, preeclampsia, and placental abruption (Backos, 1999; Rai, 1997).

In addition to IgG and IgM anticardiolipin antibodies, there are antibody idiotypes directed to a large number of lipids (Bick, 2006).

Their measurement is expensive, frequently poorly controlled, and of uncertain relevance in the diagnosis of recurrent miscarriage. Results are likewise inconclusive regarding testing for other antibodies including rheumatoid factor, antinuclear antibodies, and antithyroid antibodies.

ALLOIMMUNE FACTORS

A current and attractive theory suggests that normal pregnancy requires the formation of blocking factors that prevent maternal rejection of foreign fetal antigens that have been derived from the father. A woman will fail to produce these serum blocking factors if she shares human leukocyte antigens (HLAs) with her husband. Additional alloimmune disorders have been posited to cause recurrent miscarriage, including altered natural killer (NK) cell activity and increased lymphocytotoxic antibodies. A variety of therapies to correct these disorders has been suggested, including the use of paternal-cell immunization, third-party donor leukocytes, trophoblast-membrane infusion, and intravenous immunoglobulin. None of these has withstood rigorous scrutiny, some are potentially harmful, and thus we agree with Scott (2003) and Reddy (2007) that immunotherapy cannot be recommended.

Inherited Thrombophilias

Pathologic thrombosis results from an imbalance between clotting and anticoagulation pathways. In Fig. 6-5, the clotting cascade and some of the better described thrombophilic mutations are shown. Activation of *protein S* synergizes with activated *protein C* , thereby inhibiting the actions of clotting factors V and VIII. Thus, proteins S and C have an anticoagulant effect. Decreased action of these proteins has been postulated to increase the risk for pregnancy loss. Mutation in the gene encoding factor V results in a protein that is resistant to the effects of activated protein C (aPC). The most common of a variety of mutations is at position 506 with a glutamine substitution for arginineâ€”this FV:R506Q mutation is called the *factor V Leiden mutation* . The mutation results in a protein resistant to the effects of aPC. The net result is increased factor Vâ€“induced cleavage of prothrombin to thrombin, which causes excessive coagulability. Inherited decreased or absent *antithrombin III* activity will lead to increased thrombin formation and clotting. Mutation of the *prothrombin gene* will also result in hypercoagulability. The impact of *fibrinolytic defects* on recurrent miscarriage appears to be negligible (Sotiriadis, 2007).

FIGURE 6-5

Overview of inherited thrombophilias and their effects on the coagulation cascade.

A mutation in the gene for *methylene tetrahydrofolate reductase* causes elevated serum levels of homocysteine, which are associated with thrombosis and premature vascular disease. Hyperhomocysteinemia may also be inherited or acquired due to folic acid deficiency. In one study, elevated homocysteine levels were identified in 21 percent of women with recurrent miscarriage (Wouters, 1993)

Carp and associates (2002) and Adelberg and Kuller (2002) cast doubt on the importance of inherited thrombophilias in early miscarriage. As placental perfusion is minimal in very early pregnancy, thrombophilias may have greater clinical implications in later pregnancy. In a meta-analysis of 31 studies by Rey and colleagues (2003), recurrent miscarriage was most closely associated with the factor V Leiden and prothrombin gene mutation. Therefore, it may be reasonable to test for these mutations first in a woman with otherwise unexplained recurrent miscarriage. Treatment for the thrombophilias remains controversial, but may include heparin and aspirin. The subject was recently reviewed by Kutteh and Triplett (2006), Bick and Baker (2006), and Middeldorp (2007).

Endocrinologic Factors

Studies evaluating the relationship between various endocrinologic abnormalities have been inconsistent and have generally been

underpowered (American College of Obstetricians and Gynecologists, 2001). According to Arredondo and Noble (2006), 8 to 12 percent of recurrent miscarriages are the result of endocrine factors. Several that have been implicated are discussed.

PROGESTERONE DEFICIENCY

Insufficient progesterone secretion by the corpus luteum or placenta, also termed a *luteal phase defect* , has been suggested to cause miscarriage. Deficient progesterone production, however, may be the consequence rather than the cause of early pregnancy failure (Salem, 1984). As further discussed in Chapter 19, Serum Progesterone, the diagnostic criteria and efficacy of therapy for this proposed disorder require validation (American College of Obstetricians and Gynecologists, 2001). If the corpus luteum is removed surgically, such as for an ovarian tumor, progesterone replacement is indicated in pregnancies less than 8 to 10 weeks (Maternal Surgery).

Luteal phase defect is diagnosed when histologic dating lags behind menstrual dating by at least 2 days. The formal diagnosis also requires that two biopsies be out of phase. However, these have substantial inter- and intraobserver variability. Some have suggested that luteal phase defect can be diagnosed if the midluteal serum progesterone is less than 10 ng/mL, however, there are no studies to validate the relationship between progesterone levels and biopsy results. As many as half of women with histologically defined luteal phase defects may have normal serum progesterone levels. Furthermore, levels are frequently measured early in pregnancy, when progesterone is produced by both the corpus luteum and the trophoblast, further complicating interpretation of the results.

Treatment for presumed luteal phase defect has included progesterone supplementation, human chorionic gonadotropin administration to enhance corpus luteum function, or ovulation induction with agents such as clomiphene citrate to generate additional corpora lutea. Unfortunately, none of these treatments has been shown to be beneficial, although they are relatively benign (Reddy, 2007).

POLYCYSTIC OVARIAN SYNDROME

Women with polycystic ovaries have an increased risk for miscarriage, although the etiology remains unclear. Two main mechanisms that have been suggested are elevations in luteinizing hormone (LH) and direct effects of hyperinsulinemia on ovarian function. Both LH and β-hCG are present in the endometrium, and elevated LH concentrations may have direct deleterious effects on implantation. Another hypothesis is that chronically elevated LH levels may adversely affect oocyte development (Homburg, 1998; Watson, 1993). A third postulated mechanism is based on observations that LH induces intra-ovarian androgen levels, which are known to cause follicular atresia and poor oocyte development (Stanger, 1985; Tulppala, 1993). If we assume that elevated concentrations of LH cause miscarriage in some way, then its inhibition during a gonadotropin ovulation induction cycle might decrease miscarriage rates. In the controlled trial by Clifford (1996), however, this did not improve pregnancy outcome.

The data implicating hyperinsulinemia in pregnancy loss are somewhat stronger. Insulin modulates insulin growth factor (IGF) actions in the ovary, thereby affecting ovarian function. In one retrospective study, the miscarriage rate in women with polycystic ovarian syndrome (PCOS) was compared before and after treatment with the insulin-sensitizing medication metformin. Miscarriage rates decreased from 62 to 26 percent with treatment before and during pregnancy (Glueck, 2002). A smaller study of women with recurrent pregnancy loss was also supportive of metformin use (Jakubowicz, 2002). Taken together, these data suggest that women with PCOS who have recurrent miscarriagesâ€”and perhaps those without this historyâ€”should be treated with metformin.

DIABETES MELLITUS

Spontaneous abortion and major congenital malformation rates are both increased in women with insulin-dependent diabetes (Greene, 1999). As discussed in Diabetes Mellitus, this risk is related to the degree of metabolic control in early pregnancy. In women with recurrent miscarriage, insulin resistance has been reported to be increased (Craig, 2002). Thus, although pregnancy loss is clearly increased with poorly controlled diabetes, this risk is substantively lowered with optimal metabolic control.

HYPOTHYROIDISM

Severe iodine deficiency is associated with excessive early pregnancy loss (CastaÃ±eda, 2002). And although thyroid hormone deficiency is common in womenâ€”usually due to an autoimmune causeâ€”any effects of hypothyroidism on miscarriage have not been adequately studied. Thyroid autoantibodies are associated with an increased incidence of miscarriage, however, their role in

recurrent miscarriage is less convincing (Abramson, 2001; Esplin, 1998; Lakasing, 2005). In one investigation, Rushworth and colleagues (2000) studied 870 women with recurrent miscarriage and reported that those with antithyroid antibodies were just as likely to achieve a live birth as those without antibodies.

Because there is not a clear consensus regarding thyroid disease as a cause of recurrent miscarriage, the American College of Obstetricians and Gynecologists (2001) concludes that there is no indication for screening asymptomatic women. Conversely, overt hypothyroidism may be difficult to detect clinically, testing for it is inexpensive, and treatment is highly effective. We therefore perform thyroid-stimulating hormone (TSH) screening for women with recurrent miscarriage. We do not, however, screen for antithyroid or antimicrosomal antibodies. Although the latter provide evidence for general autoimmune dysfunction, they do not predict pregnancy loss in women with normal thyroid function (Rushworth, 2000).

Infections

As described in Infections, few infections are firmly associated with early pregnancy loss. Moreover, if any of those infections are associated with miscarriage, they are even less likely to cause recurrent miscarriage because maternal antibodies usually develop with the primary infection. Thus, there appears to be no concrete indication to screen for infection in asymptomatic women with recurrent miscarriage. Although empiric antibiotics are prescribed by some, their efficacy is unclear (Quinn, 1983a; Toth, 1986).

Evaluation and Treatment

One scheme for evaluation and treatment of women with recurrent miscarriage is outlined in Table 6-5. The timing and extent of evaluation should be based on maternal age, coexistent infertility, symptoms, and the level of anxiety. In our view, after obtaining a thorough history and examination, a modicum of testing is done. This includes parental karyotyping, uterine cavity evaluation, and testing for antiphospholipid antibody syndrome. Treatment should always be balanced between the potential morbidity and the strength of the data suggesting likely benefit.

About half of couples with recurrent miscarriage will have no explanatory findings. Nevertheless, they can be encouraged that they still may successfully achieve a live birth. The meta-analysis by Jeng and colleagues (1995) of randomized, prospective studies of couples with unexplained recurrent miscarriage determined that 60 to 70 percent had a successful subsequent pregnancy.

INDUCED ABORTION

Induced abortion is the medical or surgical termination of pregnancy before the time of fetal viability. In 2002, a total of 854,122 legal abortions were reported to the CDC (2005). These are underestimated, because clinics inconsistently report medically induced abortions. The *abortion ratio* was 246 abortions per 1,000 live births, and the *abortion rate* was 16 per 1,000 pregnant women aged 25 to 44 years. Half of these women were aged 24 years or younger, 82 percent were unmarried, and 55 percent were Caucasian. Almost 60 percent of abortions were performed during the first 8 weeks, and 88 percent during the first 12 weeks of pregnancy.

Classification of Induced Abortion

THERAPEUTIC ABORTION

Some indications for early termination of pregnancy include persistent cardiac decompensation, advanced hypertensive vascular disease, and invasive carcinoma of the cervix. In addition to medical and surgical disorders that may be indications for termination, there are others. Certainly in cases of rape or incest most consider termination indicated. Another commonly cited indication is to prevent birth of a fetus with a significant anatomic or mental deformity. The seriousness of fetal deformities is wide ranging and frequently defies social, legal, or political classification.

ELECTIVE (VOLUNTARY) ABORTION

The interruption of pregnancy before viability at the request of the woman, but not for medical reasons, is usually termed *elective* or *voluntary abortion* . These procedures comprise most abortions done today, and approximately one pregnancy is electively terminated for every four live births in the United States (Centers for Disease Control and Prevention, 2005). The Executive Board of the American College of Obstetricians and Gynecologists (2004) supports the legal right of women to obtain an abortion prior to fetal viability and considers this a medical matter between a woman and her physician.

Abortion in the United States

In 1973, the United States Supreme Court legalized abortion. Until then, only therapeutic abortions could be performed legally in most states. The most common legal definition of therapeutic abortion until then was termination of pregnancy before fetal viability for the purpose of saving the life of the mother. A few states extended their laws to read "to prevent serious or permanent bodily injury to the mother" or "to preserve the life or health of the woman". Some states allowed abortion if a pregnancy was likely to result in the birth of an infant with grave malformations.

The legality of elective abortion was established by the Supreme Court in the case of *Roe v. Wade* . The Court defined the extent to which states might regulate abortion:

1. For the stage prior to approximately the end of the first trimester, the abortion decision and the procedure must be left to the medical judgment of the attending physician.

2. For the stage subsequent to approximately the end of the first trimester, the State, in promoting its interest in the health of the mother, may, if it chooses, regulate the abortion procedures in ways that are reasonably related to maternal health.
3. For the stage subsequent to viability, the State, in promoting its interest in the potential of human life, may, if it chooses, regulate, and even proscribe abortion, except where necessary, in appropriate medical judgment, for the preservation of the life or health of the mother.

Since 1973, several other Supreme Court decisions merit citation. Borgmann and Jones (2000) have extensively reviewed these legal issues. These appellate cases originated with legislation, both state and national, that was introduced or enacted to regulate or dismantle the three provisions listed above. In general, these attempts were unsuccessful until 1989. At that time the Supreme Court ruled in the case of *Webster v. Reproductive Health Services* that states could place restrictions interfering with provision of abortion services on such items as waiting periods, specific informed consent requirements, parental/spousal notification, and hospital requirements. Based upon this decision, there are now numerous individual state restrictions that limit choice and access to abortion services. In one example, the decision to enforce parental notification in Texas in 2000 was associated with decreased abortion rates, but simultaneously increased unintended births among 17 year olds (Joyce, 2006).

Another recent choice-limiting decision is the federal law banning the poorly defined *partial birth abortion* . This law is under challenge on several fronts. The Supreme Court in mid-2007 voted 5 to 4 to uphold the Partial-Birth Abortion Act of 2003 in its review of *Gonzales v. Carhart* from Nebraska (Wright, 2006).

In its document concerning abortion policy, the American College of Obstetricians and Gynecologists (2004) states that: *The intervention of legislative bodies into medical decision making is inappropriate, ill advised, and dangerous.*

Counseling before Elective Abortion

Three choices available to a woman considering an abortion include continued pregnancy with its risks and parental responsibilities; continued pregnancy with its risks and responsibilities of arranged adoption; or the choice of abortion with its risks. Knowledgeable and compassionate counselors should objectively describe and provide information about these choices so that a woman or couple can make an informed decision.

Techniques for Early Abortion

Abortion can be performed either medically or surgically as shown in Table 6-6. Distinctive clinical features of each technique are shown in Table 6-7. Paul and colleagues (1999) summarized in detail many abortion techniques. A first-trimester pregnancy may be removed surgically by uterine curettage or by a number of medical regimens.

RESIDENCY TRAINING IN ABORTION TECHNIQUES

Because of its inherent controversial aspects, abortion training for residents in Obstetrics and Gynecology has been both championed and assailed. In some programs, such as the University of California at San Francisco, a special 6-week abortion-training elective for house staff was implemented in 1980. From 1998 through 2003, 40 residents completed training and none opted out of the rotation (Steinauer, 2005b). Other programs, such as ours at Parkland Memorial Hospital, teach residents the technical aspects of abortion by management of early missed abortions, as well as pregnancy interruption for fetal death, severe fetal anomalies, and maternal medical or surgical disorders.

Because of these differences, influenced by political and moral convictions, the American College of Obstetricians and Gynecologists (2004) respects the need and responsibility of health care providers to determine their individual positions based on personal beliefs. Certainly, physicians trained to care for women must be familiar with various abortion techniques so that complications can be managed or referrals made for suitable care (Steinauer, 2005a).

SURGICAL ABORTION

Early surgical pregnancy termination requires first dilating the cervix and then evacuating the pregnancy by mechanically scraping out the contents (sharp curettage), by suctioning out the contents (suction curettage), or both (see Sections 41-16, Sharp Dilatation and Curettage and 41-17, Suction Dilatation and Curettage). Vacuum aspiration, the most common form of suction curettage, requires a rigid cannula attached to an electric-powered vacuum source. Alternatively, manual vacuum aspiration uses a similar cannula that attaches to a handheld syringe for its vacuum source (Macisaac, 2000; Masch, 2005).

The likelihood of complications increases after the first trimester. These include uterine perforation, cervical laceration, hemorrhage, incomplete removal of the fetus and placenta, and infection. Small and large bowel injuries may also occur (Jhobta, 2007). Accordingly, sharp or suction curettage should be performed before 14 to 15 weeks.

In the absence of maternal systemic disease, abortion procedures do not require hospitalization. When abortion is performed outside a hospital setting, capabilities for cardiopulmonary resuscitation and for immediate transfer to a hospital must be available.

Hygroscopic Dilators

Trauma from mechanical dilatation can be minimized by using devices that slowly dilate the cervix. As described in Section 41-17, Suction Dilatation and Curettage, these hygroscopic dilators draw water from cervical tissues and expand, gradually dilating the cervix.

An interesting dilemma is presented by the woman who has a hygroscopic dilator placed overnight preparatory to elective abortion, but who then changes her mind. Schneider and associates (1991) described this in seven first-trimester and 14 second-trimester pregnancies. Of these, four patients returned to their original decision and underwent abortion. Of the remaining 17, there were 14 term deliveries, two preterm deliveries, and one miscarriage 2 weeks later. None suffered infectious morbidity, including three untreated women with cervical cultures positive for *Chlamydia trachomatis* . In spite of this generally reassuring report, an attitude of irrevocability with regard to dilator placement and abortion seems prudent.

Prostaglandins

Various prostaglandin preparations may be used instead of hygroscopic dilators to aid subsequent dilation. These may be taken orally or placed into the posterior vaginal fornix. In a study of self-administered misoprostol (PGE_1) at home, Oppegaard and associates (2006) reported that the oral route was unsatisfactory. Macisaac and colleagues (1999) randomized women to 400 µg of misoprostol placed vaginally 4 hours before first-trimester abortion versus laminaria placement. Misoprostol effected equal or greater dilation, caused less pain on insertion, and had fewer side effects. Timing is important, as Sharma and collaborators (2005) reported no effects with orally or vaginally administered misoprostol when given only 1 hour before early surgical abortion.

Manual Vacuum Aspiration

This office-based procedure is used for surgical treatment of early pregnancy failures as well as elective termination up to 12 weeks' gestation. Masch and Roman (2005) recommend that pregnancy terminations in the office with this method be limited to 10 weeks or less. Certainly, blood loss rises sharply between 10 and 12 weeks (Westfall, 1998).

The procedure uses a hand-operated 60-mL syringe and cannula. A vacuum is created in the syringe and attached to the cannula, which is inserted transcervically into the uterus. The vacuum is created and produces up to 60 mm Hg suction. Although complications are similar to other surgical methods, they are not increased (Goldberg, 2004).

With pregnancies less than 8 weeks, no cervical preparation is required. After this time, some recommend either osmotic dilators placed the day before or misoprostol given 2 to 4 hours before the procedure. A paracervical block with or without intravenous sedation, or conscious sedation is used for anesthesia (see Chap. 40, Usage).

Menstrual Aspiration

Aspiration of the endometrial cavity within 1 to 3 weeks after a missed menstrual period using a flexible 5- or 6-mm Karman cannula (see Fig. 41-17.3) and attached syringe has been referred to as *menstrual extraction, menstrual induction, instant period, traumatic abortion,* and *mini-abortion* . At this early gestation, pregnancy can be misdiagnosed, an implanted zygote can be missed by the curette, ectopic pregnancy can be unrecognized, or infrequently, the uterus is perforated. Even so, Paul and associates (2002) reported a 98-percent success rate in more than 1,000 women who underwent this procedure. A positive pregnancy test result will eliminate a needless procedure on a nonpregnant woman whose period has been delayed for other reasons.

To identify placenta in the aspirate, Macisaac and Darney (2000) recommend that the syringe contents are rinsed in a strainer to remove blood. They are then placed in a clear plastic container with saline and examined with back lighting. Placental tissue macroscopically appears soft, fluffy, and feathery. A magnifying lens, colposcope, or microscope can also improve visualization.

Laparotomy

In a few circumstances, abdominal hysterotomy or hysterectomy for abortion is preferable to either curettage or medical induction. If significant concurrent uterine disease is present, hysterectomy may provide ideal treatment. Either hysterotomy with tubal ligation or, on occasion, hysterectomy may be indicated for women who desire pregnancy termination and sterilization. At times, a failed medical induction during the second trimester may necessitate hysterotomy or hysterectomy.

MEDICAL ABORTION

Throughout history, many naturally occurring substances have been tried as abortifacients. Most often, serious systemic illness or even death has resulted rather than abortion. Even today, only a few effective, safe abortifacient drugs are used.

According to the American College of Obstetricians and Gynecologists (2005b), outpatient medical abortion is an acceptable alternative to surgical abortion in appropriately selected women with pregnancies less than 49 days of gestation. Beyond this point, the available data, though less robust, support surgical abortion as a preferable method of early abortion.

Three medications for early medical abortion have been widely studied and used: the antiprogestin *mifepristone* ; the antimetabolite *methotrexate* ; and the prostaglandin *misoprostol* . These agents cause abortion by increasing uterine contractility either by reversing the progesterone-induced inhibition of contractions (mifepristone and methotrexate), or by stimulating the myometrium directly (misoprostol). In addition, mifepristone causes cervical collagen degradation, possibly because of increased expression of matrix metalloproteinase-2 (Clark, 2006).

A variety of dosing schemes have proven effective (Table 6-8). Mifepristone or methotrexate is administered initially, and followed after some time interval by misoprostol. Alternatively, at least for "pregnancy failures", (i.e., anembryonic gestation, embryonic or fetal death, and incomplete or inevitable abortion), 800 µg misoprostol given vaginally as a sole agent was effective in causing complete expulsion by day 8 in 84 percent of women treated (Zhang, 2005). Methotrexate and misoprostol are teratogens, and their use thus requires a commitment on the part of both a woman and her caregiver to complete the abortion.

Table 6-8 Regimens for Medical Termination of Early Pregnancy

Mifepristone/misoprostol
[a] Mifepristone, 100â€“600 mg orally followed by:
[b] Misoprostol, 200â€“600 µg orally or 800 µg vaginally in 6â€“72 hours
Methotrexate/misoprostol
[c] Methotrexate, 50 mg/m^2 intramuscularly or orally followed by:
[d] Misoprostol, 800 µg vaginally in 3â€“7 days; repeat if needed 1 week after methotrexate initially given
Misoprostol alone
800 µg vaginally, repeated for up to three doses

[a] Doses of 200 and 600 µg are similarly effective.

[b] Oral route may be less effective, possibly more side effects (nausea and diarrhea). May also be given sub- lingually, but with more side effects.

[c] Efficacy similar for both routes of administration.

[d] Similar efficacy when given on day 3 versus day 5.

Data from the American College of Obstetricians and Gynecologists, 2005b; Borgatta, 2001; Bracken, 2007; Creinin, 2001, 2007; Hamoda, 2005; Jain, 2002; Kulier, 2004; Pymar, 2001; Schaff, 2000; Shannon, 2006; von Hertzen, 2003, 2007; Wiebe, 1999, 2002

Contraindications to medical abortion have evolved from the exclusion criteria of various clinical trials. In addition to specific allergies to the medicines, they have included an in situ intrauterine device, severe anemia, coagulopathy or anticoagulant use, and significant medical conditions such as active liver disease, cardiovascular disease, and uncontrolled seizure disorders. Additionally, because misoprostol can lower glucocorticoid activity, women with adrenal disease or with disorders requiring glucocorticoid therapy should be excluded (American College of Obstetricians and Gynecologists, 2005b). A modified methotrexate dose should be given with cautionâ€”if at allâ€”in women with renal insufficiency (Kelly, 2006). Women contemplating medical abortion should receive thorough counseling regarding the risks, benefits, and requirements of both medical and surgical approaches.

With the mifepristone regimen, according to the U.S. Food and Drug Administration (FDA) package labeling, misoprostol is to be provider-administered. Afterwards, the woman typically remains in the office for 4 hours, although her activity is not restricted. If the pregnancy appears to have been expelled, she is examined to confirm expulsion. If during observation the pregnancy does not appear to have been expelled, a pelvic examination is performed prior to discharge, and the woman re-appointed for 1 to 2 weeks. At this later appointment, if clinical examination or sonographic evaluation fails to confirm completed abortion, a suction procedure usually is done.

In regimens employing methotrexate, women are typically seen at least 24 hours after misoprostol, and approximately 7 days after methotrexate administration, at which time a sonographic examination is performed. If the pregnancy persists, another dose of misoprostol is given, and the woman is seen again in 1 week if fetal cardiac activity is present, or in 4 weeks if there is no fetal cardiac activity. If by the second visit, abortion has not occurred, it is usually completed by suction curettage.

Bleeding and cramping with medical termination can be significantly worse than symptoms experienced with menses. Adequate pain medication, usually including a narcotic, should be provided. According to the American College of Obstetricians and Gynecologists (2005b), soaking two pads or more per hour for at least 2 hours is a threshold at which a woman should be instructed to contact her provider, who can determine whether she needs to be seen.

Early medical abortion is highly effectiveâ€”90 to 98 percent of women will not require surgical intervention (Kahn, 2000). According to Hausknecht (2003), there were only 139 complications reported to the manufacturer with mifepristone when given with misoprostol to 80,000 women for medical abortion.

Unnecessary surgical intervention in women undergoing medical abortion can be avoided if sonographic results are interpreted appropriately. Specifically, if no gestational sac is present, in the absence of heavy bleeding, intervention in most women is unnecessary. This is true even when, as is common, the uterus contains sonographically evident debris.

Consequences of Elective Abortion

MATERNAL MORTALITY

Legally induced abortion, performed by trained gynecologists, especially when performed during the first 2 months of pregnancy, has a mortality rate of less than 1 per 100,000 procedures (Grimes, 2006). Early abortions are safer, and the relative risk of dying as the consequence of abortion approximately doubles for each 2 weeks after 8 weeks' gestation. According to Horon (2005), these deaths are underreported.

IMPACT ON FUTURE PREGNANCIES

In a scholarly review of the impact of elective abortion on subsequent pregnancy outcome, Hogue (1986) summarized data from more than 200 publications. Data relating abortion to subsequent pregnancy outcome are observational, and therefore subject to bias and uncontrolled confounding factors. All studies on this topic must be interpreted with these limitations in mind. That said, fertility does not appear to be diminished by an elective abortion, except infrequently as a consequence of infection. Most studies indicate that vacuum aspiration does not increase the subsequent incidence of second-trimester spontaneous abortion or preterm delivery. The case-control French EPIPAGE (epidemiologic des Petits Ages Gestationnels) study, however, found a 1.5-fold increased incidence of very preterm deliveryâ€”22 to 32 weeksâ€”in women with a history of induced abortion (Moreau, 2005). Subsequent ectopic pregnancies are not increased after elective abortion, except possibly in women with preexisting chlamydial infection or in those who develop postabortion infections. Multiple sharp curettage abortion procedures may increase the subsequent risk of placenta previa, whereas vacuum aspiration procedures likely do not (Johnson, 2003).

The recent study by Virk and colleagues (2007) of 11,814 Danish women undergoing first-trimester elective abortions is informative to compare outcomes with types of abortion. They compared subsequent pregnancy outcomes in 2,710 women undergoing medically induced termination with 9,104 who had a surgical abortion. There were no significant differences between the two groups for ectopic pregnancyâ€"about 2.5 percent, miscarriageâ€"about 6 percent, and subsequent low birthweight neonatesâ€"about 4.5 percent.

RESUMPTION OF OVULATION FOLLOWING MISCARRIAGE

Ovulation may resume as early as 2 weeks after an early pregnancy is terminated, whether spontaneously or induced. Lahteenmaki and Luukkainen (1978) detected surges of LH at 16 to 22 days after abortion in 15 of 18 women studied. Plasma progesterone levels, which had plummeted after the abortion, increased soon after LH surges. These hormonal events agree with histologic changes observed in endometrial biopsies (Boyd, 1972). **Therefore, if pregnancy is to be prevented, effective contraception should be initiated soon after abortion** .

ECTOPIC PREGNANCY: INTRODUCTION

An ectopic or extrauterine pregnancy is one in which the blastocyst implants anywhere other than the endometrial lining of the uterine cavity. In some form, they account for 1.3 to 2 percent of reported pregnancies in the United States (Zane, 2002). With the advent of a sensitive and specific radioimmunoassay for the β-subunit of human chorionic gonadotropin (β-hCG), combined with high-resolution transvaginal sonography (TVS), the initial presentation of a woman with an ectopic pregnancy is seldom life-threatening as it was in the past. Nevertheless, ectopic pregnancies remain an important cause of morbidity and mortality in the United States with an estimated total cost of nearly $295 million in 1998 (Rein, 2000).

GENERAL CONSIDERATIONS

Classification

Nearly 95 percent of ectopic pregnancies implant in the fallopian tube. Shown in Fig. 7-1 are implantation sites for 1,800 surgically treated ectopic pregnancies. Almost 95 percent were tubal pregnancies, 3.2 percent ovarian, and 1.3 percent were abdominal (Bouyer, 2002). Bilateral ectopic pregnancies are rare and their estimated prevalence is 1 of every 200,000 pregnancies (al-Awwad, 1999).

Epidemiology

Reported ectopic pregnancy incidence rates are not as reliable as in the past. The dramatic improvements in diagnosis and outpatient treatment protocols render hospital statistics invalid. According to the Centers for Disease Control and Prevention (1995), the rate of ectopic pregnancy has increased in the United States nearly fourfold, from 4.5 per 1,000 pregnancies in 1970 to 19.7 per 1,000 pregnancies in 1992. This rate is similar to recent estimates by Kaiser Permanente of North California of 20.7 per 1,000 pregnancies from 1997 to 2000 (Van Den Eeden, 2005).

A number of factors help to explain the increased incidence of ectopic pregnancies:

1. There is a greater prevalence of sexually transmitted diseases, specifically chlamydial infections (Rajkhowa, 2000).
2. Identification has improved through the use of more sensitive diagnostic tools.
3. Tubal factor infertility, including restoration of tubal patency or documented tubal pathology has increased (Ankum, 1996).
4. Delayed childbearing is more prevalent and has been accompanied by an increased use of assisted reproductive technologies, which carry increased risk of ectopic pregnancy.
5. Intrauterine device (IUD) and tubal sterilization rates have increased and failures predispose to ectopic pregnancy (Mol, 1995).

Mortality

Ectopic pregnancy remains the leading cause of early pregnancy-related death. Still, current diagnostic and treatment protocols have resulted in a 10-fold decline in the case fatality rate over the past 35 years. The rate in 1970 was 35.5 deaths per 10,000 ectopic pregnancies compared with 3.8 per 10,000 in 1989. This was despite the fivefold increase in ectopic pregnancy from 17,800 in 1970 to 108,000 in 1992 (Fig. 7-2). Racial disparities affect ectopic pregnancy-related deaths. A nonwhite woman had an overall risk of death 3.4 times higher than a white woman for the 20-year period from 1970 to 1989 (Goldner, 1993). This was true for all age groups as shown in Fig. 7-3. Inadequate access to gynecologic and prenatal care may partially explain this trend.

TUBAL RUPTURE

Rupture can lead to severe hemorrhage with resulting morbidity and mortality. Over the past two decades, the rate of rupture with ectopic pregnancy ranged from 20 to 35 percent (Job-Spira, 1999; Saxon, 1997). Three risk factors that increase the likelihood of tubal rupture include ovulation induction, serum β-hCG level exceeding 10,000 IU/L when ectopic pregnancy is first suspected, and a history of never having used contraception. Appreciation of these risk factors aids a timely diagnosis and prompt surgical intervention. Importantly, minimally invasive treatment options are limited if hemodynamic instability follows tubal rupture.

There may be a difference between an "acute" and a "chronic" ectopic pregnancy with regard to the risk of tubal rupture. Acute ectopic pregnancies are those with a high serum β-hCG level at presentation and rapid growth. These carry the highest risk of tubal rupture compared with chronic ectopic pregnancies, which demonstrate static serum β-hCG levels (Barnart, 2003c). Theoretically, an acute ectopic pregnancy has healthy growing trophoblastic cells that do not result in early bleeding, and women thus present for care later. This is compared with the chronic form, which has abnormal trophoblastic cells, which die early, have lower serum β-hCG levels, and present with early pregnancy bleeding that leads to earlier diagnosis.

Timing of tubal rupture is partially dependent on pregnancy location. As a rule, tubes rupture earlier if implantation is in the isthmic or ampullary portion. Later rupture is seen if the ovum implants within the interstitial portion. Rupture is usually spontaneous, but can also be caused by trauma such as that associated with bimanual pelvic examination or coitus.

Tubal Damage

Ultimately, there does not seem to be a direct correlation between tubal damage following ectopic pregnancy and long-term prognosis for subsequent pregnancy. Job-Spira and colleagues (1999) reported that rupture does not have an independent effect on the 1-year cumulative frequency of subsequent uterine pregnancy.

Elito and colleagues (2005) prospectively evaluated tubal patency using hysterosalpingography after conservative therapy for

ectopic pregnanciesâ€"either expectant management or systemic methotrexate. They found an initial serum β-hCG level >5000 IU/L carried a 12-fold increased risk of subsequent tubal obstruction. However, there was no relationship with obstruction and ectopic size, or sonographic landmarks such as a tubal ring seen using color flow Doppler.

PATHOPHYSIOLOGY

Histopathology

Lack of a submucosal layer within the fallopian tube wall provides easy access for the fertilized ovum to burrow through the epithelium and allow implantation within the muscular wall. As the rapidly proliferating trophoblast erodes the subjacent muscularis layer, maternal blood pours into the spaces within the trophoblast or the adjacent tissue. The lack of resistance allows early penetration by trophoblasts as shown in Fig. 7-4. The anatomic location of a tubal pregnancy may predict the extent of damage. Senterman and colleagues (1988) studied histologic samples from 84 isthmic and ampullary pregnancies and reported that half of the ampullary pregnancies were intraluminal and the muscularis was preserved in 85 percent of these. Conversely, isthmic gestations were found both intra- and extraluminally with more disruption of the tubal wall.

Inflammation

Acute inflammation has been implicated in the role of tubal damage that predisposes to ectopic pregnancies. Chronic salpingitis and salpingitis isthmica nodosa also have important roles in ectopic pregnancy development (Kutluay, 1994).

Recurrent chlamydial infection causes intraluminal inflammation and subsequent fibrin deposition with tubal scarring (Hillis, 1997). Whereas endotoxin-producing *Neisseria gonorrhoeae* causes virulent pelvic inflammation that has a rapid clinical onset, the chlamydial inflammatory response is chronic and peaks at 7 to 14 days. Persistent chlamydial antigens can trigger a delayed hypersensitivity reaction with continued scarring despite negative cultures (Toth, 2000).

Prior conservative, pharmacologically-induced abortionâ€"but not surgical terminationâ€"is associated with an increased risk for

ectopic pregnancy (Bouyer, 2003; Tharaux-Deneux, 1998). Antibiotic prophylaxis at the time of suction curettage abortion may have a protective effect from infection-related inflammatory tubal damage. For example, in a study by Sawaya and colleagues (1996), peri-procedural antibiotics decreased the risk of upper genital tract infection by 42 percent.

RISK FACTORS

An appreciation of risk factors for ectopic pregnancy leads to a more timely diagnosis with improved maternal survival and future reproductive potential. As summarized in Table 7-1, a prior ectopic pregnancy, documented tubal pathology, surgery to restore tubal patency, or tubal sterilization carry the highest risks of obstruction and subsequent ectopic pregnancy. A woman with two prior ectopic pregnancies has a 10-fold chance for another (Skjeldestad, 1998).

Table 7-1 Risk Factors for Ectopic Pregnancy

Factor	Odds Ratio (95% CI)
Prior ectopic pregnancy	12.5 (7.5, 20.9)
Prior tubal surgery	4.0 (2.6, 6.1)
Smoking >20 cigarettes per day	3.5 (1.4, 8.6)
Prior STD with confirmed PID by laparoscopy and/or positive test for *Chlamydia trachomatis*	3.4 (2.4, 5.0)
Three or more prior spontaneous miscarriages	3.0 (1.3, 6.9)

Data from Bouyer, 2003 and Buster, 1999, with permission.

Smoking, which may be a surrogate marker for sexually transmitted infections, increases the risk of ectopic pregnancy three- to fourfold in women who smoke more than one pack of cigarettes daily (Saraiya, 1998).

The use of assisted reproductive technology for sub- or infertile couples has a 0.8-percent incidence of ectopic pregnancy per transfer and 2.2 percent per clinical pregnancy (Coste, 2000). Procedures leading to the highest rates are gamete intrafallopian transfer (GIFT) (3.7 percent), cryopreserved embryo transfer (3.2 percent), and in vitro fertilization (IVF) (2.2 percent) (American Society for Reproductive Medicine and Society for Assisted Reproductive Technology, 2002). In women undergoing IVF, the main risk factors for ectopic pregnancy are tubal factor infertility and hydrosalpinges (Strandell, 1999; Van Voorhis, 2006). Moreover, "atypical" implantationâ€"cornual, abdominal, cervical, ovarian, or heterotopicâ€"is more common following assisted reproductive procedures.

Women aged 35 to 44 years have a threefold risk of ectopic pregnancy compared with those aged 15 to 25 years (Goldner, 1993). These have been attributed to age-related hormonal changes that alter tubal function (Coste, 2000).

Most forms of contraception will ironically increase the relative incidence of ectopic pregnancy by decreasing the number of intrauterine pregnancies. The relative number of ectopic pregnancies varies by contraceptive use. For example, barrier contraception and the TCu380A IUD do not confer an increased ectopic pregnancy rate (van Os, 1999). Most other forms do, and

the levonorgestrel-containing intrauterine system (Mirena, Berlex, Montville, NJ) has a 5-year cumulative pregnancy rate of 0.5 per 100 users of which half are ectopic (Backman, 2004). Progesterone-only contraceptive pills have a slightly increased rate because of their effects to diminish tubal motility. Tubal sterilization can be followed by an ectopic pregnancy. This risk is doubled in women younger than 30 years at the time of sterilization, partially because of age-related fecundity. Bipolar cautery has failure rates of 3.2 per 1000 procedures, compared with puerperal partial salpingectomy, which has a rate of 1.2 per 1000 procedures (Peterson, 1997).

CLINICAL MANIFESTATIONS

Symptoms

As women seek care earlier, the ability to diagnose ectopic pregnancy before ruptureâ€"even before the onset of symptomsâ€"is not unusual. Despite the classic symptoms of amenorrhea followed by vaginal bleeding and/or abdominal pain on the affected side, there is no constellation of symptoms that secure the diagnosis with reliability (Dart, 1999). Other pregnancy discomforts such as breast tenderness, nausea, and urinary frequency may accompany more ominous findings. These include shoulder pain worsened by inspiration, which is caused by phrenic nerve irritation from subdiaphragmatic blood, or vasomotor disturbances such as vertigo and syncope from hemorrhagic hypovolemia.

Many women with a small unruptured ectopic pregnancy have unremarkable clinical findings. Nevertheless, the diagnosis should be considered strongly when any of the above symptoms are reported by reproductive-aged women, especially those with risk factors for an extrauterine pregnancy.

Clinical Findings

VITAL SIGNS

Although some women have orthostatic findings, normal vital signs are unreliable to exclude a ruptured ectopic pregnancy. Birkhahn and associates (2003) employed the Shock Index to evaluate the possibility of ruptured ectopic pregnancy. This index reflects heart rate divided by systolic blood pressure and is used to evaluate trauma patients for hypovolemic or septic shock upon presentation. The normal range lies between 0.5 and 0.7 for nonpregnant patients. These investigators reported that a Shock Index of >0.85 increased by 15-fold the likelihood of a ruptured ectopic pregnancy.

Abdominal and pelvic findings are notoriously scant in many women before tubal rupture. With rupture, however, nearly three-fourths will have marked tenderness on both abdominal and pelvic examination and have pain that is aggravated with cervical manipulation. A pelvic mass, including fullness posterolateral to the uterus, can be palpated in about 20 percent of women. Initially, the ectopic pregnancy may feel soft and elastic, whereas extensive hemorrhage produces a firmer consistency. Many times discomfort precludes palpation of the mass, and limiting examinations may help avert iatrogenic rupture.

DIFFERENTIAL DIAGNOSIS

Symptoms of ectopic pregnancy can mimic multiple entities (Table 7-2). Early pregnancy complications such as threatened, incomplete, or missed abortion; placental polyp; or hemorrhagic corpus luteal cyst may be difficult to differentiate without histologic diagnosis (Barnhart, 2003b). Moreover, early bleeding occurs in about 20 percent of women with normal pregnancies.

Table 7-2 Conditions that Cause Lower Abdominal Pain

Cause	Location	Characteristics	Associated Findings
Pregnancy			
Abortion	Midline or generalized	Crampy, intermittent	(+) UCG; vaginal bleeding
Ectopic	Unilateral or generalized	Crampy, continuous	(+) UCG; vaginal bleeding
Uterus and Cervix			
Cervicitis	Lower abdominal pain	Dull, aching	Vaginal discharge, possible low-grade fever
Endometriosis	Midline	Variable; worse with certain activities	Adnexal mass if endometrioma present
Degenerating leiomyoma	Variable	Dull, sharp, aching	Irregular, enlarged uterus
Adnexal Disease			
Salpingitis	Diffuse	Severe	Moderate to high fever
Tubo-ovarian abscess	Unilateral	Intermittent	Usually high fever
Adnexal torsion	Lower quadrant	Acute, crampy, sudden onset	
Corpus luteum cyst	Unilateral	Sudden onset	(+/â€“) UCG
Other			
Appendicitis	Periumbilical, right lower quadrant		Anorexia, nausea, vomiting
Mesenteric lymphadenitis	Right lower quadrant		
Cystitis	Midline, suprapubic	Acute, spasms	Dysuria, frequency
Renal calculi	Flank, radiating to lower abdomen	Severe, intermittent	Hematuria

UCG = urinary chorionic gonadotropin.

A number of nonpregnancy-related disorders can mimic ectopic pregnancy (see Table 7-2). In general, a positive test for β-hCG usually excludes these other diagnoses, but the presence of a concurrent pregnancyâ€”either uterine or ectopicâ€”is always possible.

DIAGNOSIS

Serial serum β-hCG measurements and TVS are the most valuable diagnostic aids to confirm the clinical suspicions of an ectopic pregnancy.

Laboratory Findings

SERUM β-HCG MEASUREMENTS

Chorionic gonadotropin can be detected in serum as early as 8 days after the luteinizing hormone (LH) surge. In normal pregnancies, serum β-hCG levels rise in a log-linear fashion until 60 or 80 days after the last menses, at which time values plateau at about 100,000 IU/L. Given an interassay variability of 5 to 10 percent, interpretation of serial values is more reliable when performed by the same laboratory. With a robust uterine pregnancy, serum β-hCG levels should increase between 53 and 66 percent every 48 hours (Barnhart, 2004a; Kadar, 1982). Inappropriately rising serum β-hCG levels only indicate a dying pregnancy, not its location.

Many women present with an unsure last menstrual period, and an educated guess of gestational age is made. In these cases, correlation between the serum β-hCG concentration and TVS findings becomes especially important.

SERUM PROGESTERONE

Determination of serum progesterone concentration is used by some to diagnose ectopic pregnancy when serum β-hCG determinations and sonographic findings are inconclusive (Carson, 1993; Stovall, 1992). There is minimal variation in serum progesterone concentration between 5 and 10 weeks' gestation, thus a single value is sufficient. Mol and colleagues (1998) performed a meta-analysis of 22 studies to assess the accuracy of a single serum progesterone level to differentiate ectopic from uterine pregnancy. They found that results were most accurate when approached from the viewpoint of *healthy versus dying pregnancy* . With serum progesterone levels of <5 ng/mL, a dying pregnancy was detected with near perfect specificity and with a sensitivity of 60 percent. Conversely, values of >20 ng/mL had a sensitivity of 95 percent with specificity around 40 percent to identify a healthy pregnancy. Ultimately, serum progesterone can only be used to buttress a clinical impression, but cannot differentiate between an ectopic and uterine pregnancy.

HEMOGRAM

After sufficient hemorrhage, restoration of normal blood volume takes place during the following 12 to 24 hours. Resulting hemodilution causes a decrease in hemoglobin concentration or hematocrit level during this time and their serial determinations are valuable markers of hemorrhage severity. Marked leukocytosis, especially if accompanied by fever, suggests an infection-related disorder.

Sonography

High-resolution sonography has revolutionized the clinical management of a woman with a suspected ectopic pregnancy. Using TVS, a gestational sac is usually visible between 4.5 and 5 weeks, the yolk sac appears between 5 and 6 weeks, and a fetal pole with cardiac activity is first detected at 5.5 to 6 weeks (Fig. 7-5). With transabdominal sonography these structures are visualized slightly later.

FIGURE 7-5

When the last menstrual period is unknown, serum β-hCG testing is used to define expected sonographic findings. Each institution must define a β-hCG discriminatory value, that is, the lower limit at which an examiner can reliably visualize pregnancy. At most institutions, a concentration between 1,500 and 2,000 IU/L represents this value.

Accurate diagnosis by sonography is three times more likely if the initial β-hCG level is above this value. The absence of uterine pregnancy with β-hCG levels above the discriminatory value signifies an abnormal pregnancyâ€"either ectopic, incomplete abortion, or resolving completed abortion. Conversely, sonographic findings obtained when β-hCG values lie below the discriminatory value are not diagnostic in nearly two-thirds of cases (Barnhart, 1999). Moreover, routine sonography without a clinical suspicion of ectopic pregnancy does not improve diagnostic and triage efficiency.

Systematic sonographic evaluation is critical to establish the correct diagnosis. Most begin with the endometrial cavity. In pregnancies conceived spontaneously, identification of a uterine pregnancy effectively excludes the possibility of an ectopic implantation. When assisted reproductive technologies are employed, however, careful examination of the tube and ovary is performed even with a uterine pregnancy because heterotopic pregnancy rates may be as high as 1 per 100 (Tal, 1996).

An intracavitary fluid collection caused by sloughing of the decidua can create a *pseudogestational sac* , or *pseudosac* . As shown in Fig. 7-6, this one-layer sac is typically situated in the midline of the uterine cavity, whereas a normal gestational sac is eccentrically located (Dashefsky, 1988). A trilaminar endometrial pattern is unique for the diagnosis of ectopic pregnancy; its specificity is 94 percent, but its sensitivity is only 38 percent (Hammoud, 2005).

The fallopian tubes and ovaries are also inspected. Visualization of an extrauterine yolk sac or embryo clearly confirms a tubal pregnancy, although such findings are present in only 15 to 30 percent of cases (Paul, 2000). In some cases, a halo or tubal ring surrounded by a thin hypoechoic area caused by subserosal edema can be seen. According to Burry and associates (1993), this has a positive predictive value of 92 percent and a sensitivity of 95 percent. Brown and associates (1994) conducted a meta-analysis of 10 studies to ascertain the best transvaginal sonographic criteria to diagnose ectopic pregnancy. They reported that the finding of any adnexal mass, other than a simple ovarian cyst, was the most accurate, with a sensitivity of 84 percent, specificity of 99 percent, positive predictive value of 96 percent, and negative predictive value of 95 percent.

Differentiation of an ectopic pregnancy from a corpus luteal cyst can be challenging (see Chap. 9, Diagnosis and Treatment). Swire and co-workers (2004) observed that the wall of the corpus luteum is less echogenic compared with both the *halo* and the endometrium. They found that a sponge-like, lace-like, or reticular pattern seen within the cyst is classic for hemorrhage (see Fig. 9-11). With transvaginal color Doppler imaging, placental blood flow within the periphery of the complex adnexal massâ€"the *ring of fire* â€"can be seen (Fig. 7-7). Although this can help to make the diagnosis, this finding can also be seen with a corpus luteum of pregnancy (Pellerito, 1992). Pulsed-color Doppler sonographic measurements of resistance indices have been reported to help differentiate between a corpus luteal cyst and ectopic pregnancy, although poor sensitivity limits their utility (Atri, 2003a).

FIGURE 7-7

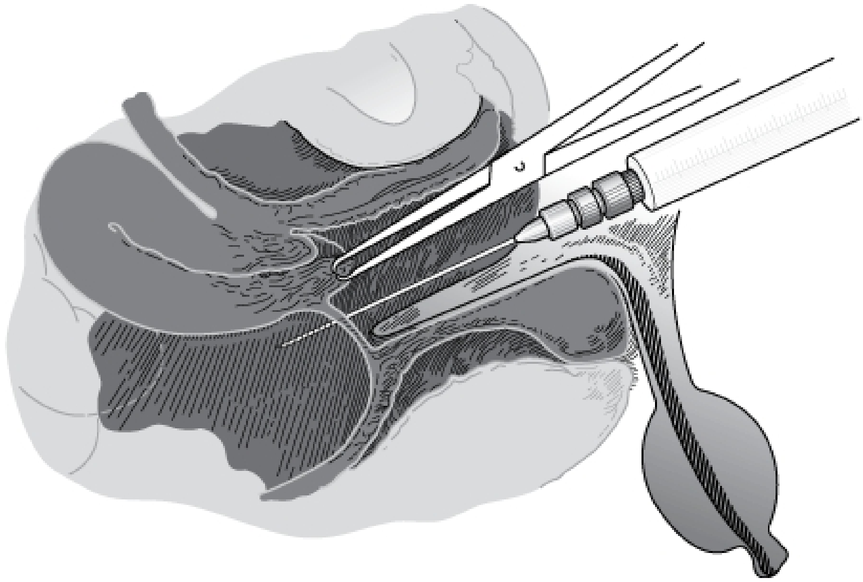
With evaluation of the pelvis, free peritoneal fluid suggests intra-abdominal bleeding. Although TVS can detect as little as 50 mL of fluid in the cul-de-sac of Douglas, transabdominal sonography helps assess the extent of hemoperitoneum. Moreover, detection of peritoneal fluid in conjunction with an adnexal mass is highly predictive of ectopic pregnancy (Nyberg, 1991).

Despite technological advances, the absence of suggestive findings does not exclude an ectopic pregnancy. In addition, TVS has not decreased the prevalence of tubal rupture or need for transfusions at the time of surgery (Atri, 2003b). However, sonography has decreased the need for diagnostic laparoscopy or curettage or both to establish the diagnosis of ectopic pregnancy. Condous and colleagues (2007) report vaginal sonography yielding the correct pre-operative diagnosis of ectopic pregnancy in nearly 91 percent of cases.

Culdocentesis

With a 16- to 18-gauge spinal needle, the cul-de-sac may be entered through the posterior vaginal fornix as upward traction is applied to the cervix with a tenaculum (Fig. 7-8). The characteristics of the aspirate, in conjunction with clinical findings, may help clarify the diagnosis. Normal-appearing peritoneal fluid is designated as a negative test. If fragments of an old clot or nonclotting blood are found in the aspirate when placed into a dry clean test tube, then hemoperitoneum is diagnosed. If the aspirated blood clots after it is withdrawn, this may signify active intraperitoneal bleeding or puncture of an adjacent vessel. If fluid cannot be aspirated, the test can only be interpreted as unsatisfactory. Finally, purulent fluid suggests a number of infection-related causes such as salpingitis or appendicitis. There also are a number of nongynecologic findings, for example, fat necrosis from pancreatitis and feculent material from a perforated or ruptured colon or an inadvertent puncture of the rectosigmoid colon.

FIGURE 7-8



Culdocentesis. *(From Nichols, 1993, with permission.)*

Historically, culdocentesis was considered an easy bedside test used to diagnose hemoperitoneum, but a number of studies contradict its usefulness. Culdocentesis has been largely replaced by TVS (Glezerman, 1992; Vermesh, 1990). Sonographic findings of echogenic fluid to establish hemoperitoneum is more sensitive and specific than culdocentesisâ€"100 and 100 percent versus 66 and 80 percent, respectively. In addition, for most women, sonography is better tolerated.

Endometrial Sampling

There are a number of endometrial changes associated with ectopic pregnancy that include decidual reactions found in 42 percent of samples, secretory endometrium in 22 percent, and proliferative endometrium in 12 percent (Lopez, 1994). Trophoblasts are not seen. Barnhart and associates (2002) recommend that absence of trophoblastic tissue be confirmed by curettage before methotrexate treatment is given. They found that the presumptive diagnosis of ectopic pregnancy is inaccurate in nearly 40 percent of cases without histologic exclusion of a spontaneous pregnancy loss. Nevertheless, the need and method of endometrial sampling must carefully be weighed against the limited risks of methotrexate.

Pipelle biopsy was studied as an alternative to curettage and found inferior, with sensitivity of obtaining villi ranging from 30 to 63 percent (Barnhart, 2003b; Ries, 2000). By comparison, frozen section of curettage fragments to identify products of conception is accurate in over 90 percent of cases (Barak, 2005; Spandorfer, 1996).

Chorionic villi in specimens from women with the diagnosis of spontaneous abortion were identified clinically in only half of cases and by the pathologist in another 30 percent. Thus in 20 percent of women, an ectopic pregnancy was still a consideration (Lindahl, 1986).

Novel Serum Markers

A number of small studies have been done to evaluate the utility of novel markers to detect ectopic pregnancy. Daniel and associates (1999) found that vascular endothelial growth factor (VEGF) in concentrations >200 pg/mL could differentiate between an ectopic and a normal or arrested uterine pregnancy with a sensitivity, specificity, and positive predictive value of 60, 90, and 86 percent, respectively. In addition, cancer antigen 125 (CA 125), serum creatine kinase, and fetal fibronectin concentrations have been investigated (Ness, 1998; Predanic, 2000). Recently, mass spectrometry-based proteomic techniques have also been used to

determine the biochemical blueprint of normal pregnancy and some of its disorders (Shankar, 2005).

SUMMARY OF DIAGNOSTIC EVALUATION

Confirmation by diagnostic laparoscopy remains the gold standard for diagnosis of ectopic pregnancy (Fig. 7-9). That said, with sensitive diagnostic modalities available, ectopic pregnancy can typically be diagnosed prior to surgery.

Use of an evidence-based algorithm will facilitate identification of an ectopic pregnancy. After appropriate clinical evaluation, all reproductive-aged women with any suspicion of pregnancy should be tested using a sensitive urine β-hCG assay. Following positive testing, if an intrauterine pregnancy is not confirmed by sonography, no signs of acute intra-abdominal hemorrhage are present, and an ectopic gestation is suspected, then an evaluation such as the one depicted by the algorithm in Figure 7-10 may be used. Gracia and colleagues (2001) performed a decision analysis of six diagnostic strategies to evaluate which sequence of tests was most efficient in yielding the fewest missed ectopic pregnancies and interrupted uterine pregnancies. They found the best strategy to be TVS for all women with first-trimester pain or bleeding. If findings are not diagnostic, then serum β-hCG levels are measured. Using this strategy, only 1 percent of all potential uterine pregnancies were interrupted, no ectopic pregnancies were missed, and the average time to diagnosis was 1.5 days. In the event that overall sensitivity of available sonography for detecting uterine pregnancy is less than 93 percentâ€”because of older sonographic equipment, an inexperienced sonographer, patient obesity or discomfort, or distorted anatomyâ€—they recommend measurement of serum β-hCG levels first, reserving sonographic examination

for those women with levels above the discriminatory zone.

A hemodynamically stable woman with vaginal bleeding, a serum β-hCG level >2,000 IU/L, and no sonographic evidence for a uterine pregnancy is a good candidate for expectant management of presumed complete abortion. Serum β-hCG levels are repeated in 24 to 48 hours to elicit the trend of change (Condous, 2005). If the rate of decline is less than 20 percent at 2 days or 60 percent at 7 days, then completed spontaneous abortion is excluded, and persistence of trophoblastic tissue from either an incomplete miscarriage or an ectopic pregnancy must be assumed (Barnhart, 2004a).

MANAGEMENT

Without intervention, an ectopic tubal pregnancy can lead to tubal abortion, tubal rupture, or spontaneous resolution. Tubal abortion is the expulsion of products through the fimbrial end. This tissue can then either regress or reimplant in the abdominal cavity. With reimplantation, bleeding or pain necessitating surgical intervention is a common complication. Tubal rupture is associated with significant intra-abdominal hemorrhage.

Medical Management

Medical therapy is preferred by most, if feasible. Only methotrexate has been extensively studied as an alternative to surgical therapy. Other agents that have been used include prostaglandins and mifepristone, as well as potassium chloride or hyperosmolar glucose injected into the ectopic mass. The best candidate for medical therapy is a woman who is asymptomatic, motivated, and has the resources to be compliant with treatment surveillance. Absolute contraindications for medical therapy include hemodynamic instability, inability to remain compliant with posttherapeutic monitoring, intrauterine pregnancy, breast feeding, and clinically important hepatic/renal dysfunction (American Society for Reproductive Medicine, 2006). With medical therapy, some classic predictors of success include:

1. Initial serum β-hCG level: This is the single best prognostic indicator of treatment success in women given single-dose methotrexate. The prognostic value of the other two predictors may be directly related to their relationship with serum β-hCG concentrations. According to Lipscomb and colleagues (1999), an initial serum value <5,000 IU/L was associated with success rates of 92 percent, whereas an initial concentration >15,000 IU/L had success rates of 68 percent. In another study, Stika and colleagues (1996) reported that women with an initial β-hCG level >5,000 IU/L were more likely to require multiple doses of methotrexate or require surgical intervention.

2. Ectopic pregnancy size: Although there are few data concerning the effect of size on success rates with medical therapy, many early trials used "large size" as an exclusion criterion. In one study, success rates with single-dose methotrexate were 93 percent in cases with ectopic masses <3.5 cm, whereas success rates were between 87 and 90 percent when the mass was >3.5 cm (Lipscomb, 1998).

3. Fetal cardiac activity: Although identification of cardiac activity sonographically is a relative contraindication to medical therapy, this is based on limited evidence. Although most studies report an increased risk of failure if there is cardiac activity, success rates of 87 percent have been reported (Lipscomb, 1998).

METHOTREXATE

This is a folic acid antagonist that competitively inhibits the binding of dihydrofolic acid to dihydrofolate reductase, which in turn reduces the amount of the active intracellular metabolite, folinic acid. This leads to diminished nucleotide precursors and limited DNA synthesis (see Chap. 27, Methotrexate). It inhibits fast-growing tissue and is used for cancer chemotherapy in conditions such as gestational trophoblastic neoplasia and for early pregnancy termination. The drug can be given orally, intravenously, intramuscularly, or be directly injected into the ectopic pregnancy sac. Currently, parenteral methotrexate administration is used most commonly.

The most common side effects of methotrexate include stomatitis, conjunctivitis, and transient liver dysfunction, although myelosuppression, mucositis, pulmonary damage, and anaphylactoid reactions have been reported with only one dose of 50 to 100 mg (Isaacs, 1996; Straka, 2004). Although these side effects are seen in as many as a third of women treated, they are usually self-limited. In some cases, leucovorin (folinic acid) is given following treatment to blunt or reverse methotrexate side effects. Such therapy is termed *leucovorin rescue* .

The single-dose and multi-dose methotrexate protocols shown in Table 7-3 are associated with overall resolution rates for ectopic pregnancy of about 90 percent. There are no randomized trials comparing single-dose versus multidose administrations. Lipscomb and colleagues (2005) reviewed their institutional experience with methotrexate therapy in 643 consecutively treated patients. They found no differences in treatment duration, serum β-hCG levels, or success rates between the multidose and single-dose protocols, 95 and 90 percent, respectively. Barnhart and Gosman (2003a) performed a meta-analysis of 26 studies that included 1,327 women treated with methotrexate for an ectopic pregnancy. Single-dose therapy was more commonly used because of simplicity. It was found to be less expensive, was easily accepted because of less intensive post-therapy monitoring, and did not require leucovorin rescue (Alexander, 1996). The major drawback was that multidose treatment had a fivefold greater chance of success than single-dose therapy (OR 4.74; CI 1.77, 12.62). Failures included women with tubal rupture, massive intra-abdominal hemorrhage, need for urgent surgery, and blood transfusions. Ultimately, most women received between one and four doses of methotrexate. Both regimens had similar side effects.

BSA = body surface area; β-hCG = β-human chorionic gonadotropin; N/A = not applicable.

In the only randomized clinical trial comparing single and multidose therapy, success rates between both treatment groups were similar (89 and 93 percent respectively) (Alleyassin, 2006). Given the convenience and efficacy, we use single dose methotrexate.

Single-Dose Methotrexate

Intramuscular methotrexate given as a single dose has been the most widely used medical treatment of ectopic pregnancy. A variety of doses has been studied, and the most popular is the 50 mg/m^2 body surface area (BSA) protocol described by the group from Memphis (Stovall, 1993). In the small randomized trial by Hajenius and colleagues (2000), treatment with 25 mg/m^2 was

equally effective as treatment with 50 mg/m^2 . Table 27-2 can be used to calculate BSA.

Close monitoring is imperative. A baseline serum β-hCG level is determined prior to methotrexate administration (Day 0). Treatment is considered Day 1 and serum β-hCG levels are repeated on days 4 and 7 following injection. Levels usually continue to rise until day 4. Of note, the serum β-hCG level on day 4 does not correlate with success of medical therapy or the need for future surgery. Comparison is then made between day 4 and 7 serum values. If there is a decline by 15 percent or more, weekly serum β-hCG levels are drawn until they measure <15 IU/L. A decline of less than 15 percent is seen in approximately 20 percent of treated women. In such cases, a second 50-mg/m^2 dose is given and the protocol repeated. Approximate time to resolution for all women averages 36 days, but in some treatment required 109 days (Lipscomb, 1998).

During the first few days following methotrexate administration, up to half of women experience a short duration of abdominal pain that can be controlled with nonsteroidal anti-inflammatory drugs. This *separation pain* presumably results from tubal distention caused by tubal abortion or hematoma formation or both (Stovall, 1993). In some cases, inpatient observation with serial hematocrit determinations and gentle abdominal examinations help assess the need for surgical intervention. Sonographic monitoring of ectopic mass dimensions can be misleading after serum β-hCG levels have declined to <15 IU/L. Brown and colleagues (1991) have described persistent masses to be resolving hematomas rather than persistent trophoblastic tissue.

Multidose Methotrexate

The most common regimen is seen in Table 7-3 and consists of up to four doses of parenteral methotrexate, followed by adjunctive doses of leucovorin 24 hours later. Serial serum β-hCG concentrations are obtained. If there is not a 15-percent decline from the previous valueâ€”for example, days 0 to 1 or days 1 to 3â€”an additional methotrexate/leucovorin dose is given, and the serum β-hCG level is repeated 2 days later. A maximum of four doses are given and weekly serum β-hCG surveillance continues until values are undetectable.

In an attempt to maximize the balance between efficacy and convenience for women undergoing methotrexate therapy for an ectopic pregnancy, Barnhart and co-workers (2007) have recently described a hybrid two-dose protocol. The preliminary study supports the safety of administering two doses of methotrexate without leucovorin rescue on days 0 and 4. Larger studies are required to confirm equivalent effectiveness.

Oral Methotrexate

Bioavailability of oral and parenteral methotrexate is similar (Jundt, 1993). There are only a few trials in which oral methotrexate was evaluated. Korhonen and colleagues (1996) randomly assigned women with tubal pregnancies without cardiac activity and serum β-hCG levels <5,000 IU/L to receive low-dose oral methotrexate, 2.5 mg daily for 5 days, or to be managed expectantly and found no differences in primary treatment success. Bengtsson and associates (1992) gave 15 mg of methotrexate orally on days 1, 3, and 5 with folinic acid on days 2, 4, and 6. This was successful in 14 of 15 women with a mean resolution time of 24 days.

Mifepristone Plus Methotrexate

It seems logical that the addition of 600 mg of mifepristone orally to single-dose methotrexate might improve efficacy and result in faster resolution of the unruptured ectopic pregnancy (see Chap. 6, Medical Abortion). In a randomized trial of 212 cases, however, Rozenberg and co-workers (2003) documented no differences in success rates.

DIRECT INJECTION INTO ECTOPIC PREGNANCY

Methotrexate

In efforts to minimize systemic side effects of methotrexate, local injection into the gestational sac under sonographic or laparoscopic guidance has been evaluated. Pharmacokinetic studies with 1 mg/kg of methotrexate injected either into the sac or intramuscularly showed similar success rates but fewer side effects with intragestational injection (Fernandez, 1994).

Hyperosmolar Glucose

In a small prospective trial, Yeko and colleagues (1995) reported that direct injection of 50-percent glucose into the ectopic mass using laparoscopic guidance was 94 percent successful in women with an unruptured ectopic whose serum β-hCG level was <2,500 IU/L. Gjelland and co-workers (1995) reported that treatment success was significantly better in a similar population in whom

sonographic- rather than laparoscopic-guided injection was used.

SURVEILLANCE

Posttherapy monitoring assesses treatment success and screens for signs of persistent ectopic pregnancy. Most medical management protocols have well-defined surveillance schedules. Kirk and colleagues (2007) prospectively tested the "day four to seven" rule in an attempt to predict success at an earlier stage and ultimately found it superior to all other combinations. In the absence of symptoms, bimanual examinations are limited to avoid theoretical risk of tubal rupture. Posttherapy sonography is reserved for suspected complications such as tubal rupture. Likewise, repeated liver function tests were not useful in the face of normal pretreatment values because very few clinically relevant abnormalities are detected (Lecuru, 2000). Most recommend contraception for 3 to 6 months after successful medical therapy with methotrexate, as this drug may persist in human tissues for up to 8 months after a single dose (Warkany, 1978).

Surgical Management

LAPAROTOMY VERSUS LAPAROSCOPY

There have been at least three prospective studies that compared open laparotomy with laparoscopic surgery for ectopic pregnancies (Lundorff, 1991; Murphy, 1992; Vermesh, 1989). Their findings are summarized below:

1. There were no significant differences in overall tubal patency determined at second-look laparoscopy. This was despite higher rates of ipsilateral adhesions in the laparotomy group.
2. Each method was followed by a similar number of subsequent uterine pregnancies.
3. There were fewer subsequent ectopic pregnancies in women treated laparoscopically, although this was not significant.
4. Laparoscopy resulted in shorter operative times, less blood loss, less analgesic requirement, and shorter hospital stays.
5. Laparoscopic surgery was significantly less successful in resolving the tubal pregnancy (RR 0.90; CI 0.83, 0.97). However, this was balanced by the above-mentioned benefits of laparoscopy.
6. The costs for laparoscopy were significantly less than for laparotomy, although some argue that costs are similar when cases converted to laparotomy are considered (Foulk, 1996).

Since completion of these studies, with improvements in laparoscopic equipment and with accrued experience, cases previously managed by laparotomy such as ruptured tubal or intact interstitial pregnancies, can now be more safely approached using laparoscopy than before (Sagiv, 2001).

LAPAROSCOPY

To date there have been no randomized trials to guide the choice between conservative (salpingostomy) and radical (salpingectomy) procedures done via laparoscopy. Retrospective reviews show equivalent subsequent uterine pregnancy rates for both conservative and radical surgery for tubal pregnancyâ€”46 and 44 percent (Clausen, 1996). Recurrent ectopic pregnancy rates are slightly higher in women having radical surgery compared with conservative techniquesâ€”15 versus 10 percent.

SALPINGECTOMY

If the contralateral fallopian tube appears normal, then salpingectomy is a reasonable treatment option that avoids the 5 to 8 percent complication rate caused by persistent or recurrent ectopic pregnancy in the same tube (Rulin, 1995). A surgical description is found in Sections 41-25, Salpingectomy and Salpingostomy and 41-30, Laparoscopic Salpingectomy.

SALPINGOSTOMY

The woman who is hemodynamically stable and strongly desires to preserve fertility is an appropriate candidate for salpingostomy. With salpingostomy, retrospective study by Milad and colleagues (1998) indicates that ectopic resolution rates were lower in women in whom the initial serum β-hCG level was <8,000 IU/L. Supportive evidence for this comes from Natale and associates (2003), who reported that serum β-hCG levels >6,000 mIU/mL have a high risk of implantation into the tubal muscular layer with subsequent tubal damage.

Medical versus Surgical Therapy

There are a number of randomized trials that have compared methotrexate treatment with laparoscopic surgery. One multicenter trial compared a multidose methotrexate protocol with laparoscopic salpingostomy and found no differences for tubal preservation and primary treatment success (Hajenius, 1997). Health-related quality of lifeâ€”pain, posttherapy depression, and decreased perception of healthâ€”was significantly impaired after systemic methotrexate compared with laparoscopic salpingostomy (Nieuwkerk, 1998). And, 61 percent of women undergoing medical therapy experienced methotrexate complications.

In comparison, single-dose methotrexate was overall less successful in resolving pregnancy than laparoscopic salpingostomy (RR 0.83; CI 0.71, 0.97), although tubal patency and subsequent uterine pregnancy were similar between both groups (Fernandez, 1998; Sowter, 2001). Women treated with methotrexate had significantly better physical functioning immediately following therapy, but there were no differences in psychological functioning.

All things considered, future reproductive potential, as defined by contralateral fallopian tube patency and subsequent intrauterine pregnancies, are similar after medical and surgical therapy (Buster and Krotz, 2007; Elito, 2006). In addition, recurrent ectopic pregnancy rates are comparable (8 percent to 13 percent) after the currently accepted methods of treatment (Buster and Krotz, 2007).

From the above, we conclude that women who are hemodynamically stable and in whom there is a small tubal diameter, no fetal cardiac activity, and serum β-hCG concentrations <5,000 IU/L have similar outcomes with medical or surgical management. Despite lower success rates with medical therapy for women with larger tubal size, higher serum β-hCG levels, and fetal cardiac activity, medical management can be offered to a motivated woman who understands the risks of emergency surgery in the event of treatment failure.

Expectant Management

In select women, some choose close observation in the event that there will be spontaneous resorption of an ectopic pregnancy. Intuitively, it is difficult to accurately predict which woman will have an uncomplicated course with such management. Although an initial serum β-hCG concentration has been shown to best predict outcome, the range varies widely. For example, initial values of <200 IU/L predict successful spontaneous resolution in 88 to 96 percent of attempts, whereas values >2,000 IU/L had success rates of only 20 to 25 percent (Elson, 2004; Trio, 1995). Even with declining values, when the initial β-hCG level exceeded 2,000 IU/L, the success rate was only 7 percent (Shalev, 1995). Interestingly, there was no difference in ipsilateral tubal patency or 1-year fertility rates with either success or failure of expectant management. Close monitoring is warranted because of reports of tubal rupture despite low and declining serum β-hCG levels. An argument could be made that minimal side effects of methotrexate make it preferable to avoid the prolonged surveillance and associated patient anxiety.

Persistent Ectopic Pregnancy

Abdominal pain after conservative surgical management of a tubal pregnancy should prompt immediate suspicion for persistent trophoblast proliferation. Incomplete removal of trophoblastic tissue and its continued growth causes tubal rupture in 3 to 20 percent of women (Graczykowski, 1999). Perhaps ironically, persistent ectopic pregnancy is more likely with very early pregnancies. Specifically, surgical management is more difficult because pregnancies smaller than 2 cm are harder to visualize and completely remove. To obviate this, Graczykowski and associates (1997) administered a prophylactic dose of 1 mg/m^2 methotrexate postoperatively, which reduced the incidence of persistent ectopic pregnancy as well as length of surveillance.

The optimal schedule to identify persistent ectopic pregnancy after surgical therapy has not been determined. Protocols describe serum β-hCG level monitoring from every 3 days to every 2 weeks. Spandorfer and associates (1997) estimated the risk of persistent ectopic pregnancy based on serum β-hCG levels done on the first postoperative day. They observed that if serum β-hCG levels fell by >50 percent compared with presurgical values, then there were no treatment failures within the first 9 days, and thus subsequent serum β-hCG determinations 1 week after surgery were appropriate. Conversely, if serum levels fell by <50 percent then there was a 3.5-fold increased risk of failure within the first week, thus necessitating earlier follow-up. Importantly, despite low and falling serum β-hCG concentrations, tubal rupture can still occur (Tulandi, 1991).

Currently, standard therapy for persistent ectopic pregnancy is single-dose methotrexate with 50 mg/m^2 BSA. Although considered,

there have been few studies to evaluate low-dose oral methotrexate for these. Bengtsson and colleagues (1992) gave 15 mg of methotrexate orally on days 1, 3, and 5, with folinic acid 30 mg on days 2, 4, and 6, and found this regimen effective in 14 of 15 women enrolled in their study.

Anti-D Isoimmunization

If the woman is D-negative and her partner has a blood group that is either D-positive or unknown, then 300 µg anti-D immune globulin should be given intramuscularly to prevent anti-D isoimmunization.

OVARIAN PREGNANCY

Ectopic implantation of the fertilized egg in the ovary is rare. The recent increased incidence likely is artifactual due to improved imaging modalities. Risk factors are similar to those for tubal pregnancies. In one study, IUD users had a higher proportion of ovarian pregnancies compared with non-usersâ€”5.5 percent versus none (World Health Organization, 1985). Nearly a third of women with an ovarian pregnancy present with hemodynamic instability because of rupture. Diagnosis is based on the classic sonographic description of a cyst with a wide echogenic outer ring on or within the ovary (Comstock, 2005).

INTERSTITIAL PREGNANCY

Also termed cornual pregnancy, interstitial pregnancies implant in the proximal tubal segment that lies within the muscular uterine wall. Swelling lateral to the insertion of the round ligament is the characteristic anatomic finding (Fig. 7-11). In the past, rupture usually followed 8 to 16 weeks of amenorrhea because of the greater distensibility of the myometrium covering the interstitial segment of fallopian tube. Risk factors are similar to others discussed, although previous ipsilateral salpingectomy is a specific risk factor for interstitial pregnancy (Lau, 1999). Because of the proximity of these pregnancies to the uterine and ovarian arteries, there is a risk of severe hemorrhage (Tulandi, 2004).

Using TVS and serum β-hCG assays as discussed for suspected tubal pregnancy, interstitial pregnancy can be diagnosed early enough to allow conservative medical or surgical therapy (Bernstein, 2001). Given the low incidence of interstitial pregnancy, no consensus regarding prediction of success using methotrexate has been established. Jermy and colleagues (2004) reported a 94 percent success rate with systemic methotrexate using 50 mg/m^2 BSA. Their series included four women in whom cardiac activity was verified. Because these women have higher initial serum β-hCG levels at diagnosis, longer surveillance is usually needed. Deruelle and co-workers (2005) advocate postmethotrexate treatment selective uterine artery embolization to help avert the risk of hemorrhage and hopefully hasten ectopic pregnancy resolution.

Surgical management involves cornual resection either at laparotomy or laparoscopy. Hysteroscopic resection of an interstitial pregnancy has been described by Sanz and Verosko (2002), but long-term results following this technique are unknown.

The risk of uterine rupture with subsequent pregnancies following either medical or conservative surgical management is unclear. Thus, careful observation of these women, along with consideration of elective cesarean delivery, is warranted.

CERVICAL PREGNANCY

The incidence of cervical pregnancy is reported to be between 1 in 8,600 to 12,400 pregnancies (Ushakov, 1997). The incidence appears to be rising because of assisted reproductive technology, especially in vitro fertilization and embryo transfer (Ginsburg, 1994; Pattinson, 1994). A risk factor unique to cervical pregnancy is a history of dilation and curettage, seen in nearly 70 percent of cases (Hung, 1996; Pisarska, 1999). Two diagnostic criteria are necessary for confirmation of cervical pregnancy: (1) the presence of cervical glands opposite the placental attachment site, and (2) a portion of or the entire placenta must be located below either the entrance of the uterine vessels or the peritoneal reflection on the anterior and posterior uterine surface.

Early diagnosis of cervical pregnancy may obviate uncontrollable hemorrhage and subsequent hysterectomy in these women. Because of its rarity, experiences with medical therapy of cervical pregnancy are limited. Systemic or intra-amnionic instillation of methotrexate was reported effective in a few cases (Hung, 1996; Kung, 1997). Surgical management involves cervical suction curettage and control of hemorrhage using Sturmdorf sutures. Because of the morbidity associated with surgical therapy, medical therapy is usually given if there is no serious bleeding at the time of discovery. In a recent report, Mesogitis and colleagues (2005) described nine women in whom 25-mg dose of methotrexate was injected directly into the amnionic sac. After documentation of trophoblastic tissue regression, cervical suction curettage was successful in all. In the event of hemorrhage, a 26-F Foley catheter with a 30-mL balloon can be placed intracervically and inflated to effect hemostasis and to monitor uterine drainage. The balloon remains inflated for 24 to 48 hours and is gradually decompressed over the next few days (Ushakov, 1997). Bilateral uterine artery embolization has also been successfully used to avert acute hemorrhage after involution and detachment of the cervical pregnancy (Trambert, 2005).

HETEROTOPIC PREGNANCY

A uterine pregnancy in conjunction with an extrauterine pregnancy is termed *heterotopic pregnancy* . In the past, incidence estimates were computed to be 1 in 30,000 pregnancies, figuring incidences of dizygotic twinning and ectopic pregnancy of 1 percent each. As a result of assisted reproductive technology, the rate of heterotopic pregnancies has literally skyrocketed to 1 in 100 pregnancies (Habana, 2000). Mechanisms that have been proposed to explain this include hydrostatic forces delivering the embryo into the cornual or tubal area, the tip of the catheter directing transfer towards the tubal ostia, or reflux of uterine secretions leading to retrograde tubal implantation.

When a tubal pregnancy coexists with a uterine pregnancy, potassium chloride can be injected into the tubal pregnancy sac. Methotrexate is contraindicated due to the detrimental effects on the normal pregnancy. Cases of craniofacial, skeletal, cardiopulmonary, and gastrointestinal anomalies have been described even with limited first-trimester methotrexate exposure (Nguyen, 2002).

CESAREAN DELIVERY SCAR PREGNANCY

Implantation within the scar of a previous cesarean delivery through a microscopic tract in the myometrium represents a rare condition carrying serious maternal morbidity and mortality from massive hemorrhage. Differentiating between a cervico-isthmic pregnancy and a cesarean delivery scar pregnancy can be difficult. According to Godin (1997), there are four sonographic criteria that must be met to secure the diagnosis: (1) an empty uterine cavity, (2) an empty cervical canal, (3) a gestational sac in the anterior part of the uterine isthmus, and (4) absence of healthy myometrium between the bladder and gestational sac. Imaging with three-dimensional color Doppler imaging provides an appreciation of the uteroplacental vascularization pattern (Chou, 2004). Also, magnetic resonance imaging can aid in the evaluation. Treatment using methotrexate, laparoscopic resection, or laparotomy is situationally dependent. Given the reportedly prolonged duration necessary to achieve complete resolution with medical treatmentâ€”3 to 4 monthsâ€”definitive devascularization might be expedited with addition of uterine artery embolization.

PREVENTION

Ectopic pregnancy is difficult to prevent because risk factors are poorly modified (Butts, 2003). Tubal pathology carries one of the highest risks and pelvic inflammatory disease plays a major role in tubal adhesions and obstruction. Because chlamydial infections constitute nearly half of pelvic inflammatory disease cases, efforts have been directed towards screening high-risk populations for asymptomatic infections (see Table 1-2). These include sexually active women under the age of 25 or women who use nonbarrier forms of contraception. Such screening programs in Sweden have demonstrated steady declines in both chlamydial infections and ectopic pregnancy rates, especially in women aged 20 to 24 years (Cates, 1999; Egger, 1998).

ABNORMAL UTERINE BLEEDING: INTRODUCTION

Regular cyclic menstruation results from the choreographed relationship between the endometrium and its regulating factors (see Chap. 15, Histologic Menstrual Cycle Changes). Changes in either of these frequently results in abnormal bleeding. Causes of this bleeding may include neoplastic growth, hormonal dysfunction, reproductive-tract trauma, infection, coagulopathies, and complications of pregnancy. As a result, abnormal uterine bleeding is a common gynecologic complaint that may affect females of all ages.

DEFINITIONS

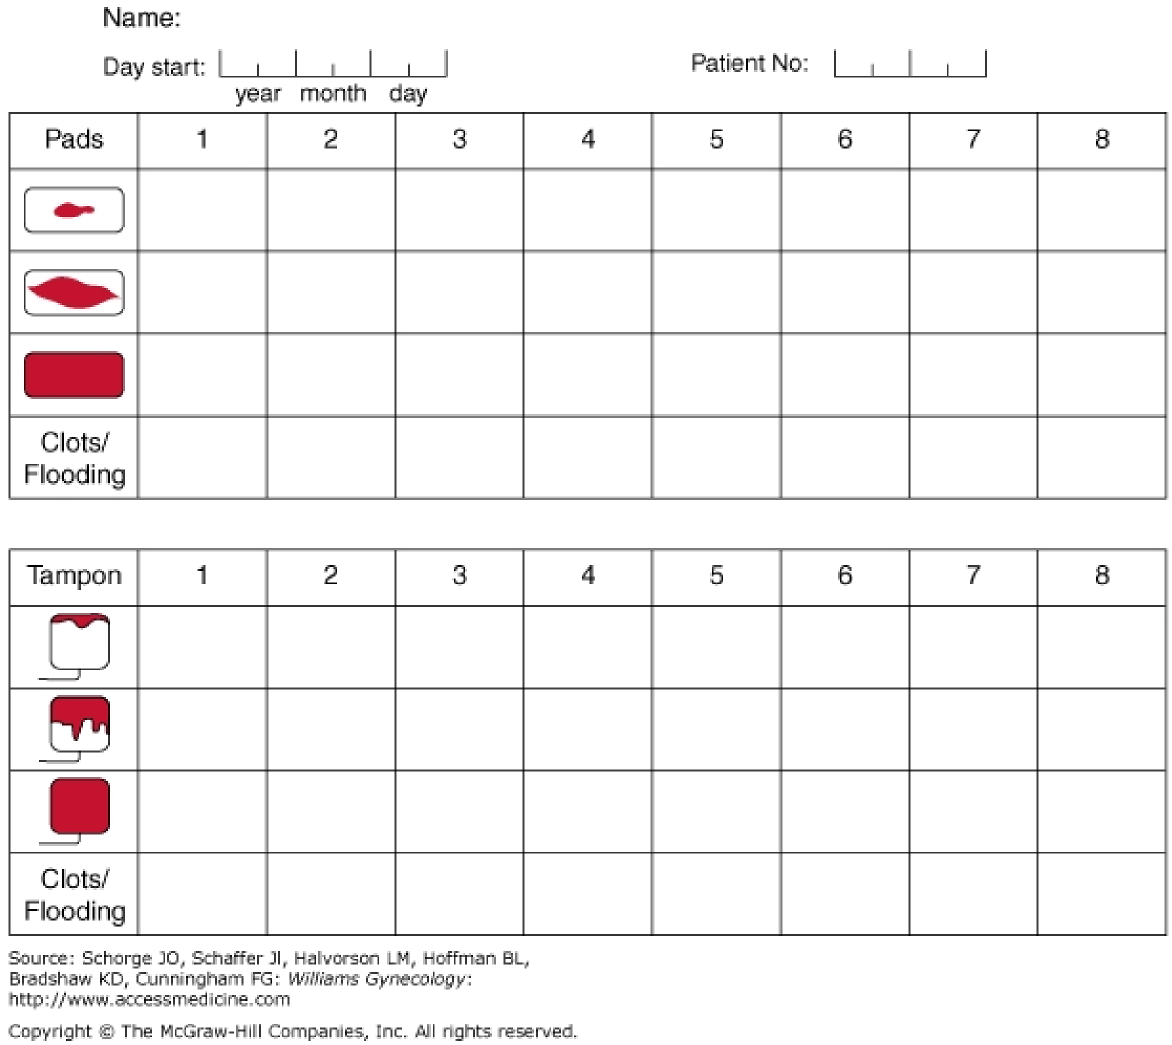
Abnormal bleeding may display several patterns. *Menorrhagia* is defined as prolonged or heavy cyclic menstruation. Objectively, menses lasting longer than 7 days or exceeding 80 mL of blood loss are determining values (Hallberg, 1966). *Metrorrhagia* describes intermenstrual bleeding. The term *breakthrough bleeding* is a more informal term for metrorrhagia that accompanies hormone administration. Frequently women may complain of both patterns, *menometrorrhagia* . In some women, there is diminished flow or shortening of menses, *hypomenorrhea* . Normal menstruation typically occurs every 28 days Â± 7 days. Cycles with intervals longer than 35 days describe a state of *oligomenorrhea* . Finally, the term *withdrawal bleeding* refers to the predictable bleeding that often results from abrupt progestin cessation.

Assessing heavy bleeding in a clinical setting has its limitations. For example, several studies have documented the lack of correlation between patient perception of blood loss and objective measurement (Chimbira, 1980c; Fraser, 1984). As a result, methods to objectively assess blood loss have been investigated. Hallberg and associates (1966) describe a technique to extract hemoglobin from sanitary napkins using sodium hydroxide. Hemoglobin is converted to hematin and can be measured spectrophotometrically. The constraints to this approach in a clinical setting are obvious.

Other tools used to estimate menstrual blood loss include hemoglobin and hematocrit evaluation. Hemoglobin concentration <12 g/dL increases the chance of identifying women with menorrhagia. A normal level, however, does not exclude menorrhagia, as many women with clinically significant bleeding have normal values.

Another method involves estimating of the number and type of pads used by a woman during menses. Warner and colleagues (2004) found positive correlations between objective menorrhagia with passing clots more than 1.1 inches in diameter and changing pads more frequently than every 3 hours. Attempts to standardize this type of evaluation have lead to development of the pictorial blood assessment chart (Fig. 8-1). Scores are assigned as follows: 1 point for each lightly stained tampon, 5 if moderately saturated, and 10 if completely soaked. Pads are similarly given ascending scores of 1, 5, and 20, respectively. Small clots score 1 point, whereas large clots score 5. Totals more than 100 points per menstrual cycle have been shown to indicate >80-mL objective blood loss (Higham, 1990; Janssen, 1995; Reid, 2000).

FIGURE 8-1



The pictorial bleeding assessment chart. Patients are counseled to evaluate the degree of saturation for each sanitary product used during menstruation. The total number of each type of sanitary product is then listed in the corresponding row during each day of menstruation. See text for assignment of points to each sanitary product and for calculation of total points. *(From Higham, 1990, with permission.)*

INCIDENCE

Abnormal uterine bleeding affects 10 to 30 percent of reproductive-aged women and up to 50 percent of perimenopausal women (Haynes, 1977; Prentice, 2000). Factors that impact the incidence most greatly are age and reproductive status. For example, uterine bleeding is uncommon in prepubertal girls and menopausal women, whereas rates of abnormal bleeding increase significantly in adolescent, perimenopausal, and reproductive-age groups. Familiarity with the most common etiologies of bleeding within these demographics often aids diagnosis and treatment (Table 8-1).

Table 8-1 Differential Diagnosis of Abnormal Bleeding

Dysfunctional uterine bleeding
Anovulatory
Perimenarchealâ€”immature hypothalamic-pituitary-ovarian axis
Perimenopausalâ€”insensitive ovarian follicles
Endocrinopathiesâ€”see systemic causes
Drugsâ€”hypothalamic depressants, steroids
Ovulatory
Organic lesions
Pregnancy-associated causesâ€”implantation spotting, abortion, ectopic pregnancy, gestational trophoblastic disease, postabortal or postpartum infection
Anatomic uterine lesions
Neoplasmâ€”leiomyoma, polyp, endometrial hyperplasia, cancer
Atrophic endometrium
Infectionâ€”sexually transmitted disease, tuberculosis
Mechanical causesâ€”intrauterine device, perforation
Arteriovenous malformation
Partial outflow obstructionâ€”congenital mÃ¼llerian defect, Asherman syndrome
Anatomic nonuterine lesions
Ovarian lesionsâ€”hormonally functional neoplasm
Fallopian tube lesionsâ€”salpingitis, cancer
Cervical and vaginal lesionsâ€”cancer, polyp, infection, atrophic vaginitis, foreign body, trauma
Systemic abnormalities
Exogenous hormone administrationâ€”sex steroids, corticosteroids
Coagulopathies
Hepatic failure
Chronic renal failure
Endocrinopathiesâ€”hypothyroidism, hyperthyroidism, adrenal disorders, diabetes mellitus, hypothalamic-pituitary disorders, polycystic ovarian syndrome, obesity

Childhood

Bleeding prior to menarche should be investigated as an abnormal finding. Initial evaluation should focus on determining the location of the bleeding, because vaginal, rectal, or urethral bleeding can present similarly. In this age group, the vagina, rather than the uterus, is the most common source of bleeding. Vulvovaginitis is the most frequent cause, but dermatologic conditions, neoplastic growths, or trauma by accident, abuse, or foreign body may also be reasons. In addition to vaginal sources, bleeding may also originate from the urethra and may reflect urethral prolapse or infection.

True uterine bleeding usually is caused by increased estrogen levels. Precocious puberty, accidental exogenous ingestion, or ovarian neoplasms should be considered in these children. Because of the risks associated with these, pelvic examination is requisite to identify the source as vaginal or uterine (Quint, 2001).

Adolescence

Abnormal uterine bleeding in adolescents results from anovulation and coagulation defects at disproportionately higher rates compared with older reproductive-aged women (Claessens, 1981; Oral, 2002; Smith, 1998). In contrast, neoplastic growths such as polyps, leiomyomas, and ovarian neoplasms are less frequent. Importantly, pregnancy, sexually transmitted diseases, and sexual abuse should not be ignored in this population.

Reproductive Age

Menorrhagia is a frequent problem in reproductive-aged women. It is estimated that a woman has a 1 in 20 lifetime chance of consulting her primary physician because of menorrhagia (Bongers, 2004).

Following adolescence, the hypothalamic-pituitary-ovarian axis matures and anovulatory uterine bleeding is encountered less frequently. With increased sexual activity, bleeding related to pregnancy and sexually transmitted disease increases. The incidence of leiomyomas and endometrial polyps increases with age, and thus bleeding from these lesions becomes common in older reproductive aged women.

Perimenopause

Abnormal uterine bleeding is a frequent clinical problem, accounting for 70 percent of all gynecologic visits by peri- and postmenopausal women. As with perimenarchal girls, anovulatory uterine bleeding from dysfunction of the hypothalamic-pituitary-ovarian axis becomes a more common finding in this group. Alternatively, the incidence of bleeding related to pregnancy and sexually transmitted disease decreases. With increasing age, there are greater risks of benign and malignant neoplastic growth. For example, Seltzer and colleagues (1990) reviewed the charts of 500 perimenopausal women and characterized alterations in their menstrual flow. They found that 18 percent had menorrhagia or metrorrhagia and one fifth of these were due to premalignant or malignant disease.

Menopause

Bleeding after menopause typically originates from benign disease. For example, Choo and colleagues (1985) found that the majority of cases resulted from atrophy of the endometrium. Benign endometrial polyps may also cause bleeding in this population.

Even so, malignant neoplasms, especially endometrial carcinoma, are found more frequently in this age group than in others. Less commonly, estrogen-producing ovarian carcinoma may cause endometrial hyperplasia with uterine bleeding. Similarly, ulcerative vulvar, vaginal, or cervical neoplasms may also be sources. And rarely, egress of serosanguineous discharge from fallopian tube cancers can appear as uterine bleeding.

As with prepubertal females, because bleeding from the rectum, vagina, or urethra may be confused by an elderly woman. Thus, clear determination of the site of bleeding is critical.

PATHOPHYSIOLOGY

The endometrium consists of two distinct zones, the functionalis layer and the basalis layer (Fig. 8-2). The basalis layer stretches beneath the functionalis, lies in direct contact with the myometrium, and is less hormonally responsive. The basalis serves as a reservoir for the regeneration of the functionalis following menses. In contrast, the functionalis layer lines the uterine cavity, undergoes dramatic change throughout the menstrual cycle, and ultimately sloughs during menstruation. Histologically, the functionalis has a surface epithelium and underlying subepithelial capillary plexus. Beneath these are organized stroma and glands in which leukocyte populations are interspersed.

Endometrial vasculature.

Blood reaches the uterus via the uterine and ovarian arteries (Fig. 38-13). From these, the arcuate arteries are formed and supply the myometrium. These in turn branch into the radial arteries, which extend toward the endometrium at right angles from the arcuate arteries (see Fig. 8-2). At the endometrium-myometrium junction, the radial arteries bifurcate to create the basal and spiral arteries. The basal arteries serve the basalis layer of the endometrium and are relatively insensitive to hormonal changes

(Abberton, 1999; Hickey, 2000b; Weston, 2000). The spiral arteries stretch to supply the functionalis layer. Their arteriole branches are thought to be critical in controlling menstruation. Prior to menses these arterioles display increased coiling with stasis of blood flow. Subsequently, vasodilatation and bleeding from the spiral arteriole and capillary walls ensues. As a result, most menstrual blood is lost through these vessels. This is followed by vasoconstriction which leads to endometrial ischemia and necrosis. This necrotic tissue is sloughed with menstruation.

SYMPTOMS

Disturbance of the endometrial degeneration and sloughing in a regular cyclic fashion results in aberrant uterine bleeding. A number of clinical manifestations can develop.

Menorrhagia and Metrorrhagia

These are defined in Definitions and describe abnormalities of bleeding patterns, duration, and flow. Most pathologic disorders, however, do not consistently display specific patterns and may cause menorrhagia or metrorrhagia or both. As a result, in many cases the bleeding pattern in a particular woman is of limited value in diagnosing the underlying cause of bleeding, but can be used to assess improvement with treatment.

Postcoital Bleeding

Bleeding following intercourse most commonly develops in women aged 20 to 40 years and in those who are multiparous. No underlying pathology is identified in up to two thirds (Rosenthal, 2001; Selo-Ojeme, 2004). If an identifiable lesion is found, however, it typically is benign (Shalini, 1998). In a review of 248 women with postcoital bleeding, Selo-Ojeme and co-workers (2004) found that a fourth of cases were caused by cervical eversion (see Chap. 29, Cervix). Other causes included endocervical polyps, cervicitis, and less commonly, endometrial polyps. In the cases of cervicitis, *Chlamydia trachomatis* is a frequent cause. Bax and associates (2002) found that the relative risk of chlamydial infection in women with postcoital bleeding was 2.6 times higher than that of a control group without bleeding.

In some women, postcoital bleeding may be from cervical or other genital tract neoplasia. The epithelium associated with cervical intraepithelial neoplasia (CIN) and invasive cancer is thin and friable and readily detaches from the cervix. In women with postcoital bleeding, CIN was found in 7 to 10 percent, invasive cancer in about 5 percent, and vaginal or endometrial cancer in <1 percent (Rosenthal, 2001; Selo-Ojeme, 2004; Shalini, 1998). In another study, Jha and Sabharwal (2002) reported that a number of women with postcoital bleeding had pathologic lesions identified at colposcopic evaluation that had been missed by Pap smear screening. Thus, most women with unexplained postcoital bleeding should undergo colposcopic examination if no other obvious source of bleeding is identified.

Pelvic Pain

Because of the role of prostaglandins in both menorrhagia and dysmenorrhea, it seems logical that painful cramping would commonly accompany abnormal bleeding (Bieglmayer, 1995; Ylikorkala, 1994). And indeed, dysmenorrhea frequently develops concurrently with abnormal bleeding caused by leiomyomas polyps, adenomyosis, infections, and pregnancy complications.

Painful intercourse and noncyclic pain are less frequent in women with abnormal bleeding and usually suggests a structural or infectious cause. For example, Lippman and colleagues (2003) reported increased rates of dyspareunia and noncyclic pelvic pain in women with uterine leiomyomas. Similarly, Sammour and co-workers (2002) correlated increasing pelvic pain with deepening myometrial invasion with adenomyosis (see Chap. 9, Adenomyosis).

DIAGNOSIS

The diagnostic goal with abnormal uterine bleeding is to exclude cancer and to identify the underlying pathology to allow optimal treatment. Technologic advances have changed the evaluation of women with abnormal uterine bleeding, and sonography, endometrial biopsy, and hysteroscopy are used primarily. Many diagnostic algorithms of uterine bleeding focus on identification of endometrial cancer (Figs. 8-3 and 8-4). Eighty to 90 percent of women with this cancer present with abnormal bleeding.

The incidence and risk of endometrial carcinoma increases with age and three fourths of women with this malignancy are postmenopausal. Thus, in postmenopausal patients, the need to exclude cancer intensifies and endometrial biopsy is warranted. In the remaining 25 percent of premenopausal women with endometrial cancer, only 5 percent are less than 40 years of age (Peterson, 1968). Most of these premenopausal women are obese or have chronic anovulation, or both (Rose, 1996). Thus, obese or anovulatory women with abnormal bleeding should also have endometrial cancer excluded. The American College of Obstetricians and Gynecologists (2000) recommends endometrial assessment in any woman older than 35 years with abnormal bleeding and in those younger than 35 years who are suspected of having anovulatory uterine bleeding refractory to medical management.

Clinical Evaluation

Initially, the site of uterine bleeding must be confirmed because bleeding may also come from the lower reproductive tract, gastrointestinal system, or urinary tract. This is more difficult when there is no active bleeding. In these situations, urinalysis or stool guaiac evaluation may be helpful adjuncts to a thorough examination.

Laboratory Evaluation

HEMATOLOGIC AND β-HCG TESTING

A hemogram is useful to evaluate anemia from chronic blood loss as well as the degree of blood loss in women with menorrhagia. An abnormally low serum ferritin level is a satisfactory predictor of blood loss >80 mL per menstrual cycle (Warner, 2004).

Pregnancy complications are quickly excluded with determination of urine or serum levels of human chorionic gonadotropin (β-hCG). Miscarriages and ectopic pregnancies may cause simple spotting or lead to life-threatening hemorrhage.

Screening for coagulation disorders should be considered in women with menorrhagia and no other obvious causes. This is particularly true for adolescents with menorrhagia. Evaluation typically includes partial thromboplastin time, prothrombin time, bleeding time, platelet count, and may include special testing for von Willebrand disease (von Willebrand Disease).

INFECTIONS

As discussed, cervicitis commonly causes intermenstrual or postcoital spotting (Lindner, 1988). In turn, the association between mucopurulent cervicitis and cervical infection with *Chlamydia trachomatis* and *Neisseria gonorrhoeae* is well established (see Chap. 3, Neisseria gonorrhoeae) (Marrazzo, 2002). The Centers for Disease Control and Prevention (2006) recommends testing for both when mucopurulent cervicitis is present. Cervicitis secondary to herpes simplex virus (HSV) infection may also cause bleeding (Paavonen, 1988).

CYTOLOGIC EXAMINATION

Both cervical and endometrial cancers can cause abnormal bleeding and evidence for these tumors can often be found with Pap smear screening.

The most frequent abnormal cytologic results involve squamous cell pathology and may reflect cervicitis, intraepithelial neoplasia, or cancer. Less commonly, atypical glandular or endometrial cells may be found. Any of these may suggest the cause of bleeding, and depending on the cytologic results, colposcopy or endometrial biopsy or both may be indicated (see Chap. 29, Colposcopy).

ENDOMETRIAL BIOPSY

Sampling and histologic evaluation of the endometrium in women with abnormal bleeding may disclose infection or neoplastic lesions such as endometrial hyperplasia, cancer, polyps, or gestational trophoblastic neoplasia (Table 8-2).

For years, dilatation and curettage (D&C) was used for endometrial tissue sampling (see Section 41-16, Sharp Dilatation and Curettage). But because of the associated surgical risks, expense, postoperative pain, and need for operative anesthesia, other suitable substitutes were evaluated. In addition, several investigators have demonstrated high rates of incomplete sampling and missed pathology with D&C (Goldstein, 1997; Grimes, 1982; Stock, 1975).

Of suitable substitutes for D&C, office techniques using metal curettes were implemented to obtain endometrial samples, and these showed significant positive correlations with histologic results from hysterectomy specimens (Ferenczy, 1979; Stovall, 1989). The main disadvantages, however, were patient discomfort, cost, and procedural complications such as uterine perforation and infection. To minimize these, a variety of thin, flexible plastic samplers have been evaluated, with comparable histologic findings from tissues obtained by D&C, hysterectomy, or stiff metal curette (Stovall, 1991). In their meta-analysis of endometrial biopsy tools, Dijkhuizen and co-workers (2000) found the Pipelle (CooperSurgical, Trumbull, CT) to be superior (Fig. 8-5).

FIGURE 8-5

During biopsy, the Pipelle is first directed to the uterine fundus (**A**). The stylette of the Pipelle is retracted to create suction within the cylinder. (**B**). The Pipelle is then drawn to the internal cervical os and advanced back to the fundus. The Pipelle is gently spun during its advancement and retraction to allow thorough sampling of all endometrial surfaces. *(From Nichols, 1993, with permission.)*

Despite its advantages, there are limitations to endometrial sampling with the Pipelle device. First, a tissue sample that is inadequate for histologic evaluation or an inability to pass the catheter into the endometrial cavity is encountered in up to 28 percent of biopsy attempts (Smith-Bindman, 1998). Cervical stenosis is the most common cause of obstruction. An incomplete evaluation necessitates further investigation with D&C, transvaginal sonography, or diagnostic hysteroscopy (Emanuel, 1995). Second, endometrial biopsy has a cancer-detection failure rate of 0.9 percent. Thus, a positive histologic result is accurate to diagnose cancer, whereas a negative result does not necessarily exclude it. Therefore, if an endometrial biopsy with normal tissue is obtained, but abnormal bleeding continues despite conservative treatment or if the suspicion of endometrial cancer is high, then further diagnostic efforts are warranted (Clark, 2002; Hatasaka, 2005). Finally, endometrial sampling is associated with a greater percentage of false-negative results if the pathology is focal, such as with endometrial polyps. Guido and associates (1995) reported false-negative results in 11 of 65 patientsâ€”17 percentâ€”undergoing Pipelle endometrial sampling for abnormal bleeding. Five of these 11 had malignant tissue present only in endometrial polyps, and another three patients had disease localized to less than 5 percent of the endometrial surface. Because of these limitations with endometrial sampling, investigators have evaluated the use of sonography, hysteroscopy, or both to replace or complement endometrial sampling.

Sonography

TRANSVAGINAL SONOGRAPHY

With its improved resolution, this technology is chosen by many instead of endometrial biopsy as a first-line tool to assess

abnormal bleeding. If abnormal bleeding stems from myometrial pathology such as leiomyomas or adenomyosis, sonography offers anatomic information regarding the myometrium that is not afforded by hysteroscopy or endometrial biopsy. In addition, transvaginal sonography (TVS) compared with these other two offers greater patient comfort and comparable detection of endometrial hyperplasia and cancer.

Endometrial thickness, which changes with the menstrual cycle (Fig. 8-6), has been correlated with endometrial cancer risk in postmenopausal women. In longitudinal views, opposed endometrial surfaces appear as a hyperechoic *endometrial stripe* down the center of the uterine body (see Fig, 2-11).

FIGURE 8-6

Variation of endometrial thickness with progression through the menstrual cycle. *(From Fleischer, 1986, with permission.)*

Although the thickness of the endometrium varies, ranges have been established. Granberg and co-workers (1991) found thickness measurements of 3.4 Â± 1.2 mm in postmenopausal women with an atrophic endometrium, 9.7 Â± 2.5 mm in those with endometrial hyperplasia, and 18.2 Â± 6.2 mm in those with endometrial cancer. Subsequently, a number of investigations have focused on endometrial thickness as it relates to the risk of hyperplasia and cancer in postmenopausal women. Sensitivities of 95 to 97 percent have been reported using a measurement of ≤4 mm for exclusion of endometrial cancer. This guideline can be employed whether or not a patient is taking hormone replacement therapy (Bakour, 1999; Karlsson, 1995; Tsuda, 1997). Women with endometrial thicknesses >5 mm warrant additional evaluation with saline-infusion sonography (SIS), hysteroscopy, or endometrial biopsy.

Endometrial thickness guidelines, however, have not been established for premenopausal women. Merz and colleagues (1996) found that the normal endometrial thickness in premenopausal women did not exceed 4 mm on day 4 of the menstrual cycle, nor did it measure over 8 mm by day 8. In their review, Farquar and co-workers (1999) suggested that a persistent finding of endometrial thickness, independent of cycle day, measuring ≥12 mm should prompt further evaluation in these women, especially

in those with risk factors for endometrial carcinoma (see Chap. 33). Risks include extended abnormal uterine bleeding, chronic anovulation, nulliparity, diabetes, obesity, hypertension, and tamoxifen use (Hatasaka, 2005).

Qualities other than endometrial thickness are also considered, and textural changes may indicate pathology. For example, punctate cystic areas within the endometrium may indicate a polyp. Conversely, hypoechoic masses that distort the endometrium and originate from the inner layer of myometrium most commonly are submucosal fibroids. Although there are no specific sonographic findings that are characteristic of endometrial cancer, some findings have been linked with greater frequency. For example, intermingled hypo- and hyperechoic areas within the endometrium may indicate malignancy. Endometrial cavity fluid collections and an irregular endometrial-myometrial junction have also been implicated. Thus, even with a normal endometrial stripe width, endometrial biopsy or hysteroscopy with biopsy should be performed to exclude malignancy when there is heterogeneous endometrial echogenicity or fluid collection (Dubinsky, 2004; Krissi, 1998; Sheikh, 2000).

Although the use of these criteria can safely reduce endometrial biopsies for many patients, others consider false-negative rates to be too high with this strategy for evaluating postmenopausal women. They advocate hysteroscopy with direct biopsy or D&C to evaluate postmenopausal bleeding (Litta, 2005; Tabor, 2002). In other patient populations, the 5-mm guideline may also be inappropriate. For example, van Doorn and co-workers (2004) reported decreased diagnostic accuracy in diabetic or obese women, and they recommend consideration of endometrial sampling.

A major limitation of TVS is the higher false-negative rate in diagnosing focal intrauterine pathology. This results in part from the physical inability of TVS to clearly assess the endometrium when there is concurrent uterine pathology such as leiomyomas or polyps. These women warrant either saline-infusion sonography or hysteroscopy for further evaluation.

SALINE-INFUSION SONOGRAPHY

This simple, minimally invasive, and effective sonographic procedure can be used to accurately evaluate the myometrium, endometrium, and endometrial cavity (see Chap. 2, Saline-Infusion Sonography). To perform SIS, a small catheter is threaded through the cervical os into the endometrial cavity. Through this catheter, sterile saline is infused, and the uterus is distended. Sonography is then performed using a traditional transvaginal technique.

This method allows visualization of common masses associated with abnormal uterine bleeding such as endometrial polyps, submucosal myomas, and intracavitary blood clots. Whereas these frequently create nondescript distortion or thickening of the endometrial lining when imaged with TVS, SIS typically permits detection of intracavitary masses as well as differentiation of lesions as being endometrial, submucosal, or intramural (Figs. 8-7 and 8-8) (Pasrija, 2004; Ryu, 2004).

Saline-infusion sonography (SIS) has also been compared with hysteroscopy to detect uterine cavitary focal lesions. De Kroon and co-workers (2003) performed a meta-analysis of 24 studies and reported SIS to equal the diagnostic accuracy of hysteroscopy.

Importantly, neither hysteroscopy nor SIS can reliably discriminate between benign and malignant focal lesions. Thus, because of the malignant potential of many focal lesions, excision of most structural lesions, when identified, is recommended for those with risk factors. For this, operative hysteroscopy is typically used.

Another disadvantage to SIS is that it is best performed in the proliferative phase of the cycle to minimize false-negative and false-positive results. For example, focal lesions may be concealed in a thick, secretory endometrium. Also, the amount of endometrial tissue that can develop during the normal secretory phase can be mistaken for small polyps or focal hyperplasia (Goldstein, 2004). For many, SIS has more patient discomfort than TVS, and about 5 percent of examinations cannot be completed because of cervical stenosis or patient discomfort. As expected, stenosis is more prevalent in postmenopausal women (De Kroon, 2003). This rate of incompletion mirrors that of diagnostic hysteroscopy.

Although accurate for identifying focal lesions, SIS may not add to the value of TVS alone to evaluate diffuse lesions such as hyperplasia and cancer. Therefore, in postmenopausal women with abnormal bleeding, and in whom the exclusion of cancer is more relevant than evaluating focal intracavitary lesions, use of SIS as an initial diagnostic tool may not have advantages over TVS alone.

TRANSVAGINAL COLOR DOPPLER SONOGRAPHY

This technique has been evaluated in identifying and differentiating endometrial pathology in the context of uterine bleeding (Alcazar, 2003, 2004; Jakab, 2005). In one study, Fleischer and colleagues (2003) used transvaginal color Doppler sonography (TV-CDS) to differentiate between submucous leiomyomas and endometrial polyps. They reported that endometrial polyps had only one arterial supply, whereas submucosal leiomyomas generally received blood flow from several vessels arising from the inner myometrium (Fig. 8-9). Others have tried unsuccessfully to measure flow impedance to determine malignant transformation within polyps. Thus, hysteroscopic excision and histopathologic evaluation of endometrial polyps are still necessary for those at risk (Endometrial Polyp) (Goldstein, 2002).

Three-dimensional sonography has been evaluated recently, but its contribution to the evaluation of abnormal uterine bleeding is also yet undefined (see Chap. 2, Three-Dimensional Sonography) (Clark, 2004; Makris, 2007).

Hysteroscopy

This procedure involves inserting an optic endoscope, usually 3 to 5 mm in diameter, into the endometrial cavity (see Section 41-35, Hysteroscopy). The uterine cavity is then distended with saline or another medium for visualization. In addition to inspection, biopsy of the endometrium allows histologic diagnosis of visually abnormal areas and has been shown to be a safe and accurate means to identify pathology (van Dongen, 2007). In fact, for many studies done to investigate the accuracy of TVS or SIS for evaluation of intracavitary uterine pathology, hysteroscopy is used as the gold standard for comparison.

The main advantage of hysteroscopy is to detect intracavitary lesions such as leiomyomas and polyps that might be missed using transvaginal sonography or endometrial sampling (Fig. 8-10) (Tahir, 1999). In fact, some have advocated hysteroscopy as the primary tool for the diagnosis of abnormal uterine bleeding. Although it is highly accurate for identifying endometrial cancer, it is less accurate for endometrial hyperplasia. Thus, some recommend endometrial biopsy or endometrial curettage in conjunction with hysteroscopy (Ben Yehuda, 1998; Clark, 2002).

There are other limitations to hysteroscopy. Cervical stenosis sometimes will block successful introduction of the endoscope, and heavy bleeding may limit an adequate examination (Beukenholdt, 2003). The use of misoprostol, 100 mg orally the evening before and the morning of hysteroscopy, is useful for cervical softening in patients with suspected cervical stenosis. Hysteroscopy is more expensive and technically challenging than TVS or SIS. Many perform hysteroscopy in their office, whereas others prefer a day-surgery setting to provide increased patient analgesia. Obviously, greater cost and anesthetic risks can attend completion in this latter setting. Although it can be painful, use of a 3.5-mm minihysteroscope instead of the conventional 5-mm endoscope significantly decreases patient discomfort during office hysteroscopy (Cicinelli, 2003). Associated infection and uterine perforation have been reported with hysteroscopy, but fortunately their incidence is low (Bradley, 2002; Vercellini, 1997).

There is concern that peritoneal seeding with malignant cells may take place during hysteroscopy in some women subsequently diagnosed with endometrial cancer (Obermair, 2000; Zerbe, 2000). Caution is advised with hysteroscopy in women at high risk for endometrial cancer, and some suggest a negative endometrial biopsy result is necessary before hysteroscopy is done (Oehler, 2003). Although there may be a risk of peritoneal contamination by cancer cells with hysteroscopy, there is no evidence that the prognosis for patients is worsened (Revel, 2004).

Summary of Diagnostic Procedures

There is no one clear sequence to use of endometrial biopsy, TVS, SIS, and hysteroscopy when evaluating abnormal uterine bleeding. None of these will distinguish all anatomic lesions with high sensitivity and specificity. That said, TVS for several reasons is a logical first step. It is well-tolerated, cost-effective, and requires relatively minimal technical skill. Additionally, it has the advantage of reliably determining whether a lesion is diffuse or focal. Once anatomic lesions have been identified, subsequent evaluation requires individualization. If endometrial hyperplasia or cancer is suspected, then endometrial biopsy may offer advantages. Alternatively, possible focal lesions may be best investigated with either hysteroscopy or SIS. Ultimately, the selection of appropriate tests depends on their accuracy to characterize the most likely anatomic lesions.

DIFFERENTIAL DIAGNOSIS

Uterine bleeding may result from hormonal changes, complications of pregnancy, coagulopathies, infection, or neoplasia. The risks and incidences of these etiologies change significantly with age and reproductive status. In approximately one half of cases, no organic pathology is identified, and dysfunctional uterine bleeding is diagnosed, that is, a diagnosis of exclusion (Rees, 1987).

External Sources

INTRAUTERINE DEVICE

Copper-Containing Intrauterine Device

These intrauterine devices (IUDs) have long been associated with menorrhagia and metrorrhagia (see Chap. 5, Menorrhagia) (Milsom, 1995; Bilian, 2002). Several explanations for this bleeding have been suggested. At the cellular level, unbalanced ratios of prostaglandins and thromboxane have been proposed as a potential source of IUD-induced menorrhagia (Zhang, 1992). This gains credence in that clinical studies have shown improvement of menorrhagia with prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs (NSAIDs) (Roy, 1981).

At the tissue level, there is increased endometrial vascularity, congestion, and degeneration in IUD users. These changes result in interstitial hemorrhage which may lead to metrorrhagia (Shaw, 1979). In another study, Pan and co-workers (1995) found more severe degenerative changes in spiral arteriolar walls with marked dilatation of lumens in women with menorrhagia and who were using an IUD. They also identified a diminished local platelet count and less fibrin thrombus in this group and suggested that IUD-related bleeding might correlate with poor spiral arteriolar contraction and inadequate thrombus formation.

At the organ level some have suggested IUD rotation, embedding, or perforation may cause excessive bleeding. There have been studies that support as well as refute this (Faundes, 1997; Pizarro, 1989).

Initially, patients with IUD-related bleeding may be managed with empiric trials of NSAIDs (Table 8-3). Persistent abnormal bleeding, however, may result from other gynecologic pathology and not from the IUD. These patients should be managed similarly to other women with the complaint of abnormal uterine bleeding. Although sonographic evaluation may be limited by IUD shadowing, endometrial biopsy with small catheters can be performed without removal of the device (Grimes, 2004).

Levonorgestrel-Containing Intrauterine System

This system, marketed as Mirena (Berlex, Wayne, NJ) (see Fig. 5-5), can lead to abnormal uterine bleeding in some users. The cause of bleeding is not clear, but downregulation of estrogen and progesterone receptors, increased local leukocyte populations, and alterations of endometrial vascular morphology, hemostasis, and endometrial repair have all been proposed (Oliveira-Ribeiro, 2004; Rhoton-Vlasak, 2005).

The endometrial effects of progestins are thought to predominate, and there is increasing evidence that low-dose progestins increase endometrial vascular fragility (Hickey, 2000a, 2002; Roopa, 2003). The LNG-IUS is associated with development of superficial, thin-walled vessels with increased diameters, that combined with irregularity of the endometrial surface, may cause the breakthrough bleeding commonly associated with its use. As the endometrium becomes atrophic, these vascular abnormalities gradually resolve at a time thought to coincide clinically with progestin-induced amenorrhea (McGavigan, 2003).

Bleeding associated with the LNG-IUS may be managed similarly to that with the copper-containing IUD, and NSAIDs serve as first-line treatment. Refractory cases warranted further evaluation for IUD displacement or intracavity pathology (Ronnerdag, 2007).

PROGESTIN-ONLY CONTRACEPTION

Bleeding disturbances are common not only with the LNG-IUS as described above, but also with other progestin-only methods of birth control. This bleeding is characteristically irregular and light, but may also be frequent and prolonged.

COMBINATION HORMONAL CONTRACEPTION

Bleeding associated with combination oral contraceptive pills (COCs) is common (see Chap. 5, Estrogen Plus Progestin Contraceptives). As many as 30 to 50 percent of women experience abnormal uterine bleeding in the first month that they use combination COCs (Hatcher, 2004). The presumed source of this bleeding stems from endometrial atrophy, which is induced by the progestin component of COCs. During this process, spiral arterioles do not characteristically coil, and they become thinner and more sinusoidal. In addition, venules become dilatated and prone to thrombosis. This often leads to local tissue infarction and is thought to be the cause of breakthrough bleeding (Deligdisch, 2000; Ober, 1977).

Fortunately, the incidence of bleeding decreases significantly with time. For example, Rosenburg and Long (1992) found that after 6 months of COC use, only approximately 10 percent of patients experienced breakthrough bleeding. Accordingly, during the early months of pill use, only counseling and reassurance are required (Schrager, 2002).

HORMONE REPLACEMENT THERAPY

Irregular spotting or bleeding is a well-known side effect of hormone replacement therapy (HRT) and is a common reason for discontinuation of treatment (see Chap. 22, Summary of Risks and Benefits) (Reynolds, 2002). Bleeding may develop both in women using continuous (daily) therapy and in those taking cyclic (sequential) replacement, but is less likely during the first year in those using a cyclic pattern (Lethaby, 2004).

TAMOXIFEN

This selective estrogen receptor modulator (SERM) is used as an adjunct for treatment of estrogen-receptorâ€"positive breast cancer. Although it diminishes estrogen action in breast tissue, its effects on the endometrium stimulate proliferation (see Chap.

12, Breast Cancer Prevention). Tamoxifen use has been linked to endometrial hyperplasia, polyps, and carcinoma as well as uterine sarcomas (Cohen, 2004).

Screening women who use tamoxifen and do not have abnormal bleeding has not proved effective. Protocols using sonography or endometrial biopsy failed to effectively identify endometrial cancer in asymptomatic users (Barakat, 2000; Love, 1999). As a result, women using tamoxifen should undergo evaluation for endometrial cancer only when bleeding develops.

Dysfunctional Uterine Bleeding

Once organic causes of abnormal uterine bleeding have been excluded, the term *dysfunctional uterine bleeding* (DUB) is used. Up to one-half of women with abnormal bleeding will have DUB (Hickey, 2000b). In 80 to 90 percent of these, bleeding results from dysfunction of the hypothalamic-pituitary-ovarian axis, which leads to anovulation (see Chap. 16). Because anovulatory cycles produce no progesterone to stabilize cyclic withdrawal of the estrogen-prepared endometrium, bleeding episodes become irregular and amenorrhea, metrorrhagia, and menorrhagia are common. For example, many women with anovulation may have amenorrhea for weeks to months followed by irregular, prolonged, and heavy bleeding.

In the other 10 to 20 percent of women with DUB, ovulation occurs cyclically, and menorrhagia is thought to originate from defects in the control mechanisms of menstruation.

PATHOPHYSIOLOGY

Anovulatory DUB

No progesterone is produced when ovulation does not occur, and thus proliferative endometrium persists. At the tissue level, presistent proliferative endometrium is often associated with stromal breakdown, decreased spiral arteriole density, and increased dilated and unstable venous capillaries (Singh, 2005). At the cellular level, the availability of arachidonic acid is reduced, and prostaglandin production is impaired. For these reasons, bleeding associated with anovulation is thought to result from changes in endometrial vascular structure and in prostaglandin concentration, and from an increased endometrial responsiveness to vasodilating prostaglandins (Hickey, 2000b, 2003).

Ovulatory DUB

Whereas anovulatory DUB results from alterations in vascular architecture and tone, ovulatory DUB is thought to stem predominantly from vascular dilatation alone. For example, women with ovulatory bleeding lose blood at rates three times faster than women with normal menses, but the number of spiral arterioles is not increased (Abberton, 1999). Thus in women with ovulatory DUB, it is thought that the vessels supplying the endometrium have decreased vascular tone and therefore increased rates of blood loss resulting from vasodilatation (Rogers, 2003). A number of causes that provoke this change in vascular tone have been suggested, and prostaglandins have been strongly implicated.

MEDICAL TREATMENT

Medical treatment of dysfunctional uterine bleeding includes tranexamic acid (antifibrinolytic agent), NSAIDs, COCs, progestins, androgens, and agonists of gonadotropin-releasing hormone (GnRH agonists) (see Table 9-3).

Nonsteroidal Anti-Inflammatory Drugs

These medicines are effective and well-tolerated oral agents commonly used for the treatment of DUB (see Table 8-3). The rationale for their use stems from the suspected role of prostaglandins in the pathogenesis of DUB. A number of investigators have documented the effectiveness of NSAIDs in decreasing DUB-related menorrhagia (Makarainen, 1986b; Marchini, 1995). Among NSAIDs, there are no differences in clinical efficacy, (Lethaby, 1998a).

Women lose 90 percent of menstrual blood volume during the first 3 days of menses (Haynes, 1977). Accordingly, NSAIDs are most effective if used with the onset of menses or just prior to its onset and continued throughout its duration. Therefore, one advantage to NSAIDs is that they are required only during menstruation. Another advantage is that commonly associated dysmenorrhea also improves with NSAIDs.

The so-called "conventional" NSAIDs nonspecifically inhibit both cyclooxygenase-1 (COX-1), an enzyme critical to normal platelet

function, and COX-2, which mediates inflammatory response mechanisms. They are effective analgesics, but their use with bleeding may not be ideal considering their inhibitory effects on platelet function. The other class of NSAIDs inhibits only COX-2 and does not interfere with platelet aggregation and hemostasis (Leese, 2000). Some have proposed that COX-2 inhibitors might be more effective to treat menorrhagia, however, there have been no randomized trials that validate this idea (Hayes, 2002). Additionally, there are now concerns that long-term use of COX-2 inhibitors is associated with increased myocardial infarction, stroke, and heart failure (Solomon, 2005). As a result, further investigation is needed before routine use of COX-2 inhibitors is recommended for menorrhagia.

Tranexamic Acid

This is an antifibrinolytic drug that exerts its effects by reversibly blocking lysine binding sites on plasminogen. The resulting decreased plasmin levels diminish fibrinolytic activity within endometrial vessels to prevent bleeding. The drug has no effect on other blood coagulation parameters such as platelet count, activated partial thromboplastin time, and prothrombin time (Wellington, 2003).

In women with DUB, there is increased fibrinolytic activity within the endometrium compared with women with normal menses (Gleeson, 1994). Clinically, the drug has been shown effective to reduce bleeding in up to half of women with DUB-related menorrhagia (Coulter, 1995; Lethaby, 2000). In addition, tranexamic acid requires administration only during menstruation and has few minor reported side effects. These are predominantly gastrointestinal and dose-dependent.

Tranexamic acid is approved for the treatment of DUB in Japan, the European Union, and Australia, as well as other countries, but not in the United States. It use has been limited by concern for complications from increased systemic thrombotic activity.

Etamsylate (Ethamsylate)

This hemostatic agent is the diethylammonium salt of dihydroxy-2,5 benzenesulphonate. It has been in clinical use for more than 30 years, but its mechanism of action is still not completely understood. Also spelled *ethamsylate,* this agent is suspected to act in early hemostasis by increasing platelet adhesiveness and aggregation (Hernandez, 2004). Its effectiveness varies in randomized trials and ranges from no reduction in flow to a 50 percent decrease (Bonnar, 1996; Chamberlain, 1991). Because of its inconsistent efficacy, in the United States, etamsylate does not have a clinical role in the treatment of menorrhagia (Irvine, 1999).

Oral Progestins

As discussed earlier, unopposed estrogen stimulation, resulting from anovulatory cycles, causes proliferation of the endometrium and erratic bleeding. Progestins halt endometrial growth and allow for an organized sloughing with their withdrawal (Saarikoski, 1990). Thus, progestin treatment of women with anovulatory DUB is usually successful. Of the oral progestins, either norethindroneâ€”also known as norethisteroneâ€”or medroxyprogesterone acetate may be used. For immediate control of bleeding, norethindrone, 5 mg, is given two or three times daily, or medroxyprogesterone acetate 10 mg is taken once daily for 10 days. This is followed by withdrawal bleeding 3 to 5 days after completion of the either course. For long-term management, similar dosages of these drugs are given during days 16 through 25 following commencement of the most recent menstrual flow (Fraser, 1990). Again, withdrawal bleeding will follow cessation each month.

In contrast, ovulatory menorrhagia is not due to a progestin deficiency but may result from altered prostaglandin synthesis or disruption of hemostasis. As expected, ovulatory menorrhagia is relatively unresponsive to cyclic administration of oral progestins (Cameron, 1987, 1990; Preston, 1995; Singh, 2005).

Despite this, women with ovulatory DUB may respond to longer treatment schedules. Norethindrone 5 mg or medroxyprogesterone acetate 10 mg, each given three times orally daily for days 5 to 26 of each menstrual cycle have been shown effective (Fraser, 1990; Irvine, 1998). Unfortunately, prolonged use of high-dose progestins is often associated with side effects such as mood changes, weight gain, bloating, headaches, and atherogenic changes in the lipid profile (Lethaby, 1998b). For these reasons, they are considered unacceptable by many women for long-term use.

Combination Oral Contraceptive Pills

Evidence suggests that these hormonal contraceptives are effective in the treatment of DUB, and when used long term, reduce flow

by 40 to 70 percent (Agarwal, 2001; Fraser, 1991). Advantages to COC use include the additional benefits of reducing dysmenorrhea and providing contraception (see Chap. 5, Estrogen Plus Progestin Contraceptives). Their presumed method of action is endometrial atrophy. There may also be diminished prostaglandin synthesis and decreased endometrial fibrinolysis (Irvine, 1999).

In addition to chronic use for the treatment of dysfunctional uterine bleeding, COCs can be used acutely to manage menorrhagia. Pills containing at least 30 μg of ethinyl estradiol should be prescribed. If there is active bleeding, the regimen begins with four pills every 6 hours until the bleeding has stopped for at least 24 hours. An antiemetic may be needed to control nausea. For most women, bleeding will cease within 48 hours. After the bleeding has stopped, the dosage of COC is decreased to three pills per day for the next 3 days, followed by two pills per day for 3 days. A once-a-day regimen is then continued for 21 days to be followed by withdrawal menses. At this point, COCs may be stopped or continued for cycle control (Rimsza, 2002). Alternatively, less frequent dosing or smaller doses may also be effective in the acute management of menorrhagia.

Estrogen

High-dose estrogen therapy may be useful in controlling acute bleeding episodes because it promotes rapid endometrial growth to cover denuded surfaces. Conjugated equine estrogens (Premarin, Wyeth Pharmaceuticals, Madison, NJ) are administered orally at dosages up to 10 mg daily given in four divided doses. Similarly, the drug can be given intravenously in 25-mg doses every 4 hours for up to three doses (DeVore, 1982). Once bleeding has slowed, patients can be transitioned to an oral taper using COCs.

Androgens (Danazol and Gestrinone)

Danazol is an isoxazole derivative of the synthetic steroid 17α-ethinyl testosterone (see Chap, 10, Androgens). The net effect of danazol creates a hypoestrogenic and hyperandrogenic environment, which induces endometrial atrophy. As a result, menstrual loss is reduced by approximately half, and it may even induce amenorrhea in some women (Beaumont, 2002; Chimbira, 1980a; Higham, 1993).

For heavy menstrual bleeding, suggested dosing is 100 to 200 mg taken orally every day (Chimbira, 1980b). Unfortunately, this agent has significant androgenic side effects that include weight gain, oily skin, and acne. It is thus usually reserved as a second-line drug for short-term use prior to surgery (Bongers, 2004).

Gestrinone is derived synthetically from a 19-nortestosterone steroid nucleus. Its mechanism of action, side effects, and indications for the treatment of menorrhagia are similar to danazol. The recommended dose for the treatment of menorrhagia is 2.5 mg daily every 3 to 4 days. The drug is used in the United Kingdom and other countries, but is not approved for use in the United States.

Gonadotropin-Releasing Hormone Agonists

The profound hypoestrogenic state created by these agents induces endometrial atrophy and amenorrhea in most women (see Chap. 9, GnRH Agonists). Side effects, however, may be dramatic and include those typical for the menopause (see Chap. 21, Hypothalamus-Pituitary-Ovarian Axis Changes). In addition, associated bone loss precludes their long-term use. This family of drugs, however, may be helpful for short-term use in inducing amenorrhea and allowing women to rebuild their red blood cell mass prior to surgery.

Levonorgestrel-Containing Intrauterine System

Intrauterine devices were developed for contraceptive purposes, but the levonorgestrel-containing intrauterine system (LNG-IUS) also provides relief of menorrhagia for some women (see Chap. 5, Levonorgestrel-Containing Intrauterine Device).

The addition of progestins to inert intrauterine devices was found to decrease expulsion, improve contraceptive action, and in some cases, improve menorrhagia (Barrington, 1997). The LNG-IUS device was designed to take advantage of these attributes, and it has been shown to reduce menstrual loss by 74 to 97 percent after 3 months use (Singh, 2005; Stewart, 2001). The LNG-IUS can be used in all women as a first line of treatment of menorrhagia in place of oral medications. It is particularly useful for reproductive-aged women who also desire contraception.

SURGERY

For many women, conservative medical management may either be unsuccessful or associated with significant side effects. For

women whose symptoms are poorly managed with medical options, surgical management of menorrhagia may include procedures to destroy the endometrium and hysterectomy.

Dilatation and Curettage (D&C)

Curettage is rarely used for long-term treatment because its effects are only temporary. In the occasional woman, D&C is performed to arrest severe bleeding refractory to high-dose estrogen administration (American College of Obstetricians and Gynecologists, 2000; Stabinsky and associates 1999). An illustrated description of D&C is found in Section 41-16, Sharp Dilatation and Curettage.

Endometrial Destructive Procedures

Although medical therapy is generally used first, over half of women with menorrhagia undergo hysterectomy within 5 years of referral to a gynecologist. In at least a third of these, an anatomically normal uterus is removed (Coulter, 1991; Roy, 2004). As alternatives to hysterectomy, less invasive procedures have been devised that either destroy or resect the endometrium and lead to amenorrhea in a manner similar to Asherman syndrome (see Section 41-36, Endometrial Ablation Procedures).

It is problematic that endometrial tissue has tremendous regenerative capabilities. For this reason, to be successful, destructive procedures must remove the endometrial functionalis and basalis as well as 3 mm of myometrial depth. However, the persistence or regeneration of endometrium is possible. Therefore, premenopausal women should be counseled before surgery about the need for adequate postoperative contraception.

In addition, the American College of Obstetricians and Gynecologists (2007) recommends endometrial sampling prior to surgery. Women with endometrial hyperplasia or cancer should not undergo ablation.

Currently acceptable procedures for endometrial resection or ablation use laser, radiofrequency, electrical, or thermal energies (Oehler, 2003). They are described as either first- or second-generation techniques according to their temporal introduction into use and their need for hysteroscopic guidance. A number of studies that compare first- and second-generation techniques have shown them equally effective (Gervaise, 1999; Meyer, 1998).

Both first- and second-generation procedures require dilation of the cervix to admit the ablative device. They are typically performed using general anesthesia or conduction analgesia. However, some have described the use of paracervical block and/or intravenous sedation for second-generation procedures (Fernandez, 1997; Soysal, 2001; Wallage, 2003). Recently, Marsh and co-workers (2005) described the use of thermal balloon ablation using only preoperative ibuprofen.

There are three first-generation methods. Two of these, the neodymium:yttrium-aluminum-garnet (Nd-YAG) laser and rollerball destroy the endometrium. In contrast, the third method, transcervical resection of the endometrium (TCRE), surgically removes it. All three require advanced operative hysteroscopic skills and a fluid distention medium. Complications from excess systemic absorption of these media can be severe and are discussed in Section 41-35, Hysteroscopy.

After resection or ablation, 70 to 80 percent of women experience significantly decreased bleeding, and 15 to 35 percent of these develop amenorrhea. Increasing treatment failures due to endometrial regeneration accrue with time following the procedure. For example, in a long-term surveillance of 301 women following ablation, Martyn and co-workers (1998) reported that the cumulative failure rate increased from 13 percent at 2 years to 27 percent at 5 years. Long-term surveillance of women following ablation shows an approximate 20 percent ultimate hysterectomy rate (Aberdeen Endometrial Ablation Trials Group, 1999; Furst, 2007).

Although success rates for treatment of heavy bleeding are not as high as with hysterectomy, patient satisfaction rates are surprisingly comparable. Moreover, resection and ablation procedures have significantly lower complication rates when compared with hysterectomy.

Hysterectomy

Removal of the uterus is obviously the most effective treatment for bleeding and overall patient satisfaction rates approximate 85 percent. Moreover, subjective improvement of dysmenorrhea and premenstrual symptoms has also been reported following hysterectomy (Aberdeen Endometrial Ablation Trials Group, 1999; Mousa, 2001). Disadvantages to hysterectomy include more frequent and severe intraoperative and postoperative complications compared with either conservative medical or ablation procedures. Operating time, hospitalization, recovery times, and costs are also greater. The procedure is discussed in detail in Section 41-19, Hysterectomy.

Structural Abnormalities

PATHOLOGY ASSOCIATED WITH UTERINE ENLARGEMENT

Structural abnormalities are common causes of abnormal bleeding, and of these, leiomyomas by far are the most common. The impact of these tumors in clinical gynecology cannot be overstated. Less frequent structural causes of bleeding include adenomyosis, hematometra, and hypertrophic myometrium. A detailed discussion of these disorders and their treatment is presented in Chapter 9, Uterus.

MÃ¼LLERIAN DEFECTS

Congenital structural lesions of the reproductive tract may at times cause chronic intermenstrual bleeding superimposed upon normal menstrual cycles (see Chap. 18, Description and Patient Presentation). In such cases, an anomalous partial vaginal septum may collect blood behind it. Although sequestered, a small patent outflow from the collection typically allows chronic release. Patients thus describe cyclic menses with light but persistent intermenstrual flow.

ARTERIOVENOUS MALFORMATION

A uterine arteriovenous malformation (AVM) is a mixture of arterial, venous, and small capillary-like channels with fistulous connections. They may be congenital or acquired. The size of the vessels varies considerably and they may be large and tortuous or much smaller and uniform (Majmudar, 1998). Acquired AVMs are usually single, large vessels that result from trauma at cesarean delivery or D&C, from cervical or endometrial cancer, from gestational trophoblastic disease, or from IUD use (Ghosh, 1986). Uterine AVMs are rare. They more commonly involve the corpus, but are also found in the cervix (Lowenstein, 2004).

Affected patients commonly present with menorrhagia or menometrorrhagia soon after a miscarriage, uterine surgery, or curettage. Heavy uterine bleeding without associated cervical trauma or uterine perforation may be presenting signs. Additionally, uterine atony that fails to respond to conventional therapies should raise suspicion for this abnormality following delivery (Chang, 2004). Symptoms can appear slowly or suddenly and with life-threatening bleeding (Timmerman, 2003).

In some cases, AVMs are first visualized with sonography because of its ready availability and widespread use. Sonographic characteristics are nonspecific and may include hypoechogenic tubular structures within the myometrium. Color Doppler sonography may provide a more specific image with thickened vessels and blood flow reversals. Angiography is used to confirm the diagnosis of AVMs, although computed-tomography (CT) scanning with contrast, magnetic resonance (MR) imaging saline-infusion sonography, and hysteroscopy have also been described (Lowenstein, 2004; Timmerman, 2003).

Arteriovenous malformations have been treated traditionally by hysterectomy. A number of investigators, however, have demonstrated the effectiveness of arterial embolization of feeder vessels (Halperin, 2007; Majmudar, 1998).

ENDOMETRIAL POLYP

These soft, fleshy intrauterine overgrowths are comprised of endometrial glands and fibrotic stroma and are covered by a surface epithelium (Fig. 8-10 and 8-11). Polyps are common, and their prevalence ranges from 10 to 30 percent in women with abnormal bleeding (Bakour, 2000; Goldstein, 1997). As shown in Figure 8-11, intact polyps may be single or multiple, may measure from a few millimeters to several centimeters, and may be sessile or pedunculated with a long and slender stalk (Kim, 2004). Most polyps are benign, but hyperplasia develops frequently. Moreover, malignant transformation develops in 1 to 2 percent of polyps (Ben Arie, 2004; Machtinger, 2005; Savelli, 2003).

FIGURE 8-11

Several factors have been implicated in the growth of endometrial polyps. Gene translocations involving chromosomes 6 and 12 have been linked with polyp development (Vanni, 1993; Dal Cin, 1992). Some studies implicate estrogen and progesterone as important mediators because they cause endometrial glands, stromal tissue, and spiral arteries to elongate, which gives the characteristic polypoid appearance to these growths (Jakab, 2005).

The few risk factors associated with development of endometrial polyps include hypertension and obesity as well as tamoxifen use (Reslova, 1999). Most evidence does not support a link between hormone replacement therapy and polyp formation (Bakour, 2002; Lahti, 1993; Maia, 2004).

More than 70 percent of women with endometrial polyps will complain of menorrhagia or metrorrhagia (Preutthipan, 2005; Reslova, 1999). It is thought that stromal congestion within the polyp leads to venous stasis with apical necrosis and bleeding (Jakab, 2005). Although bleeding is common, with the introduction of transvaginal sonography, a large number of women with asymptomatic polyps have been identified during imaging for other indications (Goldstein, 2002).

Infertility has been indirectly linked to some endometrial pathology. Small studies have shown increased pregnancy rates and fewer early pregnancy losses in infertile women following hysteroscopic excision (Preutthipan, 2005; Shokeir, 2004; Varasteh, 1999). Moreover, a randomized trial by Perez-Medina (2005) demonstrated a doubling of the pregnancy rate following intrauterine insemination (IUI) in infertile women following polypectomy compared with a group with polyps and infertillity managed with IUI alone. Although the exact mechanisms related to infertility are unknown, several causes have been suggested. Metalloproteinases associated with implantation and cytokines that impact embryo development have been implicated. Both are found in greater amount in polyps than normal surrounding uterine tissue (Inagaki, 2003). Alternatively, some investigators have found polyps in disproportionate numbers near the tubal ostia, and these may hinder ostium function and affect sperm migration (Shokeir, 2004;

Venturini, 1987). For these reasons, many advocate polyp removal in infertile women.

Although the risk of malignant transformation within polyps is low, it is more common with increasing age, hypertension, tamoxifen use, and polyp size greater than 1.5 cm. In some studies, malignant transformation has been reported only in postmenopausal patients (Anastasiadis, 2000; Cohen, 2004).

Transvaginal sonography, SIS, and hysteroscopy have evolved as the main diagnostic tools for evaluation of endometrial polyps. Although endometrial biopsy may identify polyps, it has decreased sensitivity for detecting focal lesions compared with these imaging modalities.

In premenopausal women with abnormal bleeding, TVS is best performed prior to day 10 of the cycle to lower the risk of false-positive findings. Using TVS, an endometrial polyp may appear as a nonspecific endometrial thickening or as round or elongated focal masses within the endometrial cavity (Fig. 8-7). Sonolucent cystic spaces corresponding to dilated endometrial glands may be seen within some polyps (Nalaboff, 2001).

Transvaginal sonography may be augmented with color Doppler. Visualization of a single feeding vessel is typical of endometrial polyps as shown in Figure 8-9 (Fleischer, 2003). Unfortunately, flow impedance measurements using color Doppler have failed to accurately determine the malignant potential of these lesions. Thus, excision and histopathologic evaluation of polyps are still necessary in those with risk factors (Goldstein, 2002).

Saline-infusion sonography (SIS) and hysteroscopy are both highly accurate in imaging endometrial polyps (see Figs. 8-8 and 8-10) (Nanda, 2002; Soares, 2000). Using SIS, polyps appear as echogenic, smooth, intracavitary masses with either broad bases or thin stalks and are outlined by fluid (Jorizzo, 2001). Hysteroscopy identifies nearly all cases of endometrial polyps (see Fig. 8-10). The main advantage of hysteroscopy is the ability to identify and often remove the polyp concurrently.

Whereas the Pap smear is not an effective tool to identify polyps, occasionally it incidentally leads to their identification. For example, 5 percent of postmenopausal women with benign endometrial cells identified on Pap smear were found to have endometrial polyps (Wu, 2001; Karim, 2002). Moreover, in those with atypical glandular cells, endometrial polyps were the most common underlying pathology found by investigators (Obenson, 2000).

Once a polyp has been identified, operative hysteroscopy is often the treatment of choice. The technique is detailed in Section 41-38, Polypectomy. Hysteroscopy and polypectomy is recommended for symptomatic women or for those with risk factors for malignant transformation (Savelli, 2003; Machtinger, 2005). Conversely, asymptomatic premenopausal women with polyps <1.5 cm can be observed. There is only a small associated risk of malignant transformation and high rates of spontaneous resolution (Ben Arie, 2004; DeWaay, 2002).

ENDOCERVICAL POLYP

These lesions represent overgrowths of benign endocervical stroma covered by epithelium. They appear as single, red, smooth elongated masses extending from the external os (see Fig. 4-13). Polyps vary in size and range from several millimeters to 2 or 3 cm. These common growths are found more frequently in multiparas and rarely in prepubertal females. Endocervical polyps are typically asymptomatic, but they can cause metrorrhagia, postcoital bleeding, and symptomatic vaginal discharge.

Endocervical polyps are usually identified by visual inspection during pelvic examination. In some instances, Pap smear findings of atypical glandular cells have been associated with endocervical polyps (Burja, 1999; Obenson, 2000). Although typically benign, malignant transformation may develop in 1 percent. Importantly, cervical cancer can present as polypoid masses and can mimic these benign lesions. For this reason, removal and histologic evaluation are recommended for an endocervical polyp.

Endocervical polyps are removed by grasping the polyp with a ring or polyp forceps. The polyp is twisted repeatedly about the base of its stalk to strangulate its feeding vessels. With repeated twisting the base will avulse. Monsel solution (ferric subsulfate) can be applied with direct pressure to the resulting stalk stub to complete hemostasis.

Infection

In addition to cervicitis, chronic endometritis can also lead to abnormal bleeding. Chronic endometritis was found by Greenwood and colleagues (1981) in 3 to 10 percent of endometrial biopsies performed for abnormal bleeding. Although bleeding is common

with chromic endometritis, women may also complain of vaginal discharge and lower abdominal pain. Chronic endometritis may develop insidiously, and usually follows abortion, pregnancy, and pelvic inflammatory disease (PID). As discussed further in Chapter 3, Diagnosis abnormal uterine bleeding may be observed in some women with acute as well as subclinical or silent PID (Ness, 2004; Wiesenfeld, 2002).

Diagnosis is made with endometrial biopsy. Women with biopsy-proven endometritis frequently have other lower genital tract infection concurrent with endometritis (Korn, 1995; Toth, 2007). In one study, Wiesenfeld and co-workers (2002) found subclinical PID and endometritis in 27 percent of women with Chlamydia trachomatis, in 26 percent of women infected with *Neisseria gonorrhoeae,* and in 15 percent of those with bacterial vaginosis. Antibiotic treatment comparable to that for PID usually results in cessation of bleeding symptoms (Eckert, 2004).

Pregnancy Associated

Abnormal bleeding during early pregnancy is encountered in 15 to 20 percent of pregnancies (Everett, 1997; Weiss, 2004). Although frequently no reason is found to account for bleeding, it may reflect early abortion, ectopic pregnancy, cervical infection, or polyp. A detailed discussion of bleeding associated with pregnancy is found in Chapters 6, Threatened Abortion and 7, Symptoms. The almost universal availability of sonography and β-hCG testing have revolutionized the assessment of bleeding in this setting.

Systemic Causes

RENAL DISEASE

Severe renal dysfunction is frequently accompanied by endocrine disturbances with amenorrhea, hypoestrogenism, and infertility (Matuszkiewicz-Rowinska, 2004). In a study of 100 women with chronic renal failure undergoing dialysis, Cochrane and Regan (1997) reported that 80 percent of those menstruating complained of menorrhagia. The mechanism behind these abnormalities is not clear, but hypothalamic dysregulation of gonadotropin secretion is suspected (Bry-Gauillard, 1999).

Treatment of abnormal bleeding due to chronic renal insufficiency is problematic. Prostaglandin synthase inhibitors are contraindicated because they cause renal artery vasoconstriction with adverse effects on glomerular function. Administration of cyclic progestins is typically unhelpful, and instead, Cochrane and Regan (1997) suggest high-dose medroxyprogesterone acetate to cause amenorrhea from endometrial atrophy. They also reported that most women with renal insufficiency respond to low-dose COCs, which offer the additional benefit of improved cycle control. However, in women with severe hypertension, these are typically contraindicated.

If women with severe menorrhagia cannot take or do not respond to medical therapy, then surgical treatments are considered. Jeong and co-workers (2004) found endometrial ablation to be successful, with 87 percent of women showing improvement of abnormal bleeding. In some women, however, hysterectomy is required.

LIVER DISEASE

Depending on its severity, liver dysfunction causes high rates of menstrual abnormalities (Stellon, 1986). In studies evaluating menstruation in women with end-stage liver disease before transplantation, menstrual dysfunction is reported in 60 percent (de Koning, 1990; Mass, 1996). The underlying mechanism for bleeding is not clear, but as in renal failure, hypothalamic-pituitary-ovarian (HPO) axis dysfunction has been implicated. The liver serves a primary role in the metabolism and excretion of sex hormones, and liver dysfunction is associated with high levels of circulating estrogen. In addition, there may be inappropriately low serum LH and FSH levels, indicating dysfunction of the HPO axis (Bell, 1995; Cundy, 1991).

Hemostatic dysfunction may also contribute to abnormal bleeding. With the exception of von Willebrand factor, all of the coagulation proteins and most of their inhibitors are synthesized in the liver. In addition, thrombocytopenia is common in women with portal hypertension and splenomegaly.

THYROID DISEASE

Both hyperthyroidism and hypothyroidism can cause menstrual disturbances ranging from amenorrhea to menorrhagia (Koutras, 1997). Although thyroid dysfunction can result in a spectrum of symptoms, in many women, menstrual abnormalities antedate

other clinical findings of thyroid disease (Joshi, 1993). Thus, in most women with abnormal uterine bleeding, serum thyroid-stimulating hormone (TSH) level measurement is recommended.

With hyperthyroidism, hypomenorrhea and amenorrhea are more frequent complaints. Menorrhagia is noted in only about 5 percent. Treatment of thyrotoxicosis improves menstrual regularity in most cases.

Women with severe overt hypothyroidism commonly present with anovulation, amenorrhea, and anovulatory DUB (Chap. 16, Hyperprolactinemia and Hypothyroidism). These women may also display defects in hemostasis. This may be due to decreased levels of several coagulation factors that have been identified in these women. Treatment of the underlying hypothyroidism usually corrects bleeding dysfunction (Krassas, 1999; Wilansky, 1989).

COAGULOPATHY

Whereas hemostatic defects are infrequent causes of gynecologic bleeding, in the subset of women with menorrhagia and normal anatomy, the incidence is significantly higher (Kadir, 1998; Philipp, 2005).

The American College of Obstetricians and Gynecologists (2001) recommends testing for bleeding disorders in: (1) adolescents with severe menorrhagia, (2) women with significant menorrhagia without another identifiable cause, and (3) preoperatively, prior to hysterectomy planned for severe bleeding. The initial screening evaluation of bleeding disorders in general has included a prothrombin time (PT), partial thromboplastin time (PTT), platelet count, and bleeding time. More commonly identified coagulopathies include von Willebrand disease (vWD) and other disorders of platelet function. Deficiencies of factor VII and IX (hemophilia A and B) or other factor deficiencies are more rarely involved.

Thrombocytopenia

Platelets are an integral part of thrombus formation. Their concentration in blood varies during the menstrual cycle, increasing following ovulation and falling at the onset of menses. In some women, clinically significant changes in platelet count or function can lead to abnormal bleeding.

von Willebrand Disease

Von Willebrand factor (vWF) is a large multimeric glycoprotein integral to hemostasis. It acts as an adhesive protein in clot formation at sites of vessel injury. It also prevents inactivation and clearance of factor VIII, which is depleted rapidly without vWF and becomes clinically deficient (Mendolicchio, 2005). There are several variants of the disease that are determined by the amount and function of vWF produced (Table 8-6).

Table 8-6 Phenotypic Classification and Genetic Transmission of von Willebrand Disease.

Phenotype	Mechanism of Disease	Genetic Transmission
1	Partial quantitative deficiency of von Willebrand factor (and factor VIII)	Autosomal dominant[a]
2	Qualitative defects of von Willebrand factor	Autosomal dominant[b]
3	Severe or complete deficiency of von Willebrand factor and moderately severe factor VIII deficiency	Autosomal recessive

[a] This mode of transmission is sometimes not evident because of reduced penetrance and varied expressivity.

[b] Rare cases are characterized by autosomal recessive transmission.

Adapted from Mannucci, 2004a, with permission.

Consideration of von Willebrand Disease (vWD) in young women is important because its prevalence is 1 to 2 percent in the general population (Rodeghiero, 1987). In women with abnormal bleeding and normal pelvic anatomy, rates of vWD were found to be 13 percent (Shankar, 2004). The disorder is more common in Caucasian than in African-American women (Miller, 2003).

Patients with vWD commonly complain of menorrhagia, and rates of 60 to 70 percent have been noted (Kadir, 1998, 1999; Lak, 2000). Heavy menstruation begins with menarche in these patients. Moreover, they commonly have other bleeding symptoms such as easy bruising, bleeding from the nose or gums, and postpartum or postoperative bleeding (Lee, 2005).

Testing for this bleeding disorder should be considered when evaluating women with menorrhagia for coagulopathies. Depending on the type and severity of vWD, the PTT and bleeding time may be prolonged. The American College of Obstetricians and Gynecologists (2001) recommends the ristocetin cofactor assay (vWF:RCo) to aid diagnosis. Importantly, vWF levels may be higher during the luteal phase, and thus samples should be obtained prior to day 7 of the menstrual cycle (Kadir, 1999; Lee, 2005). Consultation with a hematologist is recommended because diagnosis of vWD, especially in its mild form, is difficult.

Treatments for women with menorrhagia and vWD include desmopressin, plasma concentrates, hormonal contraception, antifibrinolytics, and surgery. Combination oral contraceptive pills have been noted to arrest uterine hemorrhage in 88 percent of women (Foster, 1995). Also, Kingman and co-workers (2004) reported that the LNG-IUS effectively decreased blood loss and induced amenorrhea in 56 percent of women with inherited bleeding disorders. Preliminary success has been found with endometrial ablation for women with vWD-related menorrhagia (El-Nashar, 2007; Rubin, 2004). Hysterectomy, of course, is curative and preoperative consultation with a hematologist is recommended.

For severe bleeding, replacement of vWF and factor VIII by plasma concentrates is given along with desmopressin. This vasopressin analog promotes release of vWF from storage sites in patients with the common type 1 vWD. The drug is available in an intravenous and a concentrated intranasal form (Lee, 2005).

Coagulation Factor Deficiencies

A number of these may result in menorrhagia. Deficiency of a procoagulant factor usually manifests as a prolonged prothrombin time or activated partial thromboplastin time.

Hemophilia A and B are inherited X-linked deficiencies of factor VIII or IX. Women carriers of the gene, however, can have decreased levels of factor VIII or IX. In some cases, these are low enough to cause mild hemophilia (Mannucci, 2001; Siegel, 2005).

Deficiencies of other coagulation factors are usually inherited as autosomal recessive traits and are rare. This group includes dysfibrinogenemia, hypofibrinogenemia, prothrombin deficiency, and deficiency of factors V, VII, X, XI, and XIII. Treatment of these disorders is by factor replacement (Mannucci, 2004b).

PELVIC MASS: INTRODUCTION

Pelvic masses are common clinical findings and may involve the reproductive organs or nongynecologic structures. They may be identified in asymptomatic women during routine pelvic examination or may cause symptoms. Typical complaints include pain, pressure sensations, dysmenorrhea, or abnormal uterine bleeding. Although most pelvic masses are acquired lesions, a few arise as congenital anomalies. As a part of evaluation, laboratory tests are typically uninformative, but levels of serum β-human chorionic gonadotropin (β-hCG) or tumor markers may be helpful. Initially, imaging with sonography is preferred, but computed tomography (CT) or magnetic resonance (MR) imaging may be useful if the nature of the mass is still uncertain. Treatment of pelvic masses varies with patient symptoms, age, and risk factors. Although medical management is possible for many of these masses, for others, surgical treatment offers the highest success rates.

DEMOGRAPHIC FACTORS

Age has the greatest influence in evaluation of a pelvic mass. Pathology varies greatly with age, and neoplasms are more prevalent in older women.

Prepubertal Girls

The majority of gynecologic pelvic masses in this age group involve the ovary. Even during childhood, the ovaries are typically active, and many of these masses are functional cysts (de Silva, 2004; Deligeoroglou, 2004). Neoplastic lesions usually are benign germ cell tumors, and mature cystic teratomas (dermoid cysts) are the most common (Brown, 1993; Templeman, 2000). Malignant ovarian tumors in children and adolescents are rare and account for only 0.9 percent of all malignancies in this age group (see Chap. 36) (Young, 1975).

Adolescents

For the most part, the incidence and type of ovarian pathology found in adolescents is similar to those seen in prepubertal girls. With the onset of reproductive function, however, pelvic masses in adolescents may also include endometriomas and the sequelae of pelvic inflammatory disease and pregnancy. Gynecologic masses present a special diagnostic challenge in children and adolescents, because benign neoplasms greatly outnumber malignant ones, and their clinical signs and symptoms are often nonspecific. Multimodal techniques for diagnosis in these age groups are discussed in Chapter 14, Prepubertal Ovarian Cysts.

Reproductive-Aged Women

A number of genital tract disorders cause pelvic masses in adult women. Uterine enlargement due to pregnancy, functional ovarian cysts, and leiomyomas are among the most common. Endometrioma, mature cystic teratoma, acute or chronic tubo-ovarian abscess, and ectopic pregnancies are other frequent causes.

Postmenopausal Women

With the cessation of ovulation and reproductive function, the causes of pelvic mass also change. Simple ovarian cysts and leiomyomas are still a common source. Although atrophy of leiomyomas typically follows menopause, uterine enlargement can still be noted in many women. Importantly, malignancy is a more frequent cause of pelvic masses in this demographic group. Uterine tumors, including adenocarcinoma and sarcoma, have associated uterine enlargement. In addition, ovarian cancer accounts for nearly 4 percent of cancers among all women, with an estimate of over 25,000 new cases diagnosed annually in the United States (Barnholtz-Sloan, 2003).

UTERUS

Uterine enlargement is common and most frequently is the result of pregnancy or leiomyomas. Less often, enlargement is from adenomyosis, hematometra, or an adherent adnexal mass.

Leiomyomas

Leiomyomas are benign smooth muscle neoplasms that typically originate from the myometrium. They are often referred to as *uterine myomas,* and are incorrectly called *fibroids* because the considerable amount of collagen contained in many of them creates a fibrous consistency. Their incidence among women is generally cited as 20 to 25 percent, but has been shown to be as high as 70 to 80 percent in studies using histologic or sonographic examination (Buttram, 1981; Cramer, 1990; Day Baird, 2003).

In many women, leiomyomas are clinically insignificant. Conversely, in some, their number, size, or location within the uterus can provoke a myriad of symptoms. Taken together, symptoms caused by these uterine tumors constitute an important segment of gynecologic practice.

PATHOLOGIC APPEARANCE

Grossly leiomyomas are round, pearly white, firm, rubbery tumors that on cut-surface display a whorled pattern. A typically involved uterus contains 6 to 7 tumors of varying size (Cramer, 1990). Leiomyomas possess a distinct autonomy from their surrounding myometrium because of a thin outer connective tissue layer. This clinically important arrangement allows leiomyomas to be easily "shelled out" of the uterus during surgery.

Histologically, leiomyomas contain elongated smooth muscle cells aggregated in bundles that swirl and intersect at right angles to one another. Mitotic activity, however, is rare and is a key point in differentiation from leiomyosarcoma (see Chap. 34, Leiomyosarcoma) (Zaloudek, 2002).

The appearance of leiomyomas may vary when normal muscle tissue is replaced with various degenerative substances following hemorrhage and necrosis. This process is collectively termed *degeneration,* and these gross changes should be recognized as normal variants (Fig. 9-1). Degeneration develops frequently in leiomyomas because of the limited blood supply within these tumors. Leiomyomas have a lower arterial density compared with the surrounding normal myometrium (Fig. 9-2). Moreover, there is no intrinsic vascular organization and this disorganization leaves some tumors vulnerable to hypoperfusion and ischemia (Farrer-Brown, 1970; Forssman, 1976). Acute pain may accompany degeneration.

CYTOGENETICS

Each leiomyoma is derived from a single progenitor myocyte. Thus, multiple tumors within the same uterus each show independent cytogenetic origins (Mashal, 1994; Townsend, 1970). The primary mutation initiating tumorigenesis is unknown, but identifiable karyotypic defects are found in about 40 percent of leiomyomas (Rein, 1998; Xing, 1997). A number of unique defects involving chromosomes 6, 7, 12, and 14 have been identified to correlate with rates and direction of tumor growth (Brosens, 1998). It is anticipated that further characterization of the specific functions of these karyotypic changes will help to define the important steps in leiomyoma development.

ROLE OF HORMONES

Estrogens

Uterine leiomyomas are estrogen- and progesterone-sensitive tumors (Table 9-1). Consequently, they develop during the reproductive years and regress in size and incidence after menopause. This concept is integral in understanding many of the risk factors associated with leiomyoma development and in formulating treatment plans. Sex steroid hormones likely mediate their effect by stimulating or inhibiting transcription and production of cellular growth factors.

Table 9-1 Relationships of Patients Factors, Leiomyoma Risk, and Steroid Hormones

Factor	Effect on Risk	Potential Reason
Postmenopausal	Decreased	Hypoestrogenism
Early menarche	Increased	Increased years of estrogen exposure
Obesity	Increased	Increased conversion of androgens to estrogens
Pregnancy	Decreased	Break in chronic estrogen exposure; uterine remodeling during postpartum involution
Combination oral contraceptives	Decreased	Exposure to estrogen opposed by progesterone
Cigarette smoking	Decreased	Decreased serum estrogen levels
African-American race	Increased	Genetic differences in hormone production or metabolism
Affected family member	Increased	Genetic differences in hormone production or metabolism

Leiomyomas themselves create a hyperestrogenic environment, which appears requisite for their growth and maintenance. First, compared with normal myometrium, leiomyomas contain a greater density of estrogen receptors that results in greater estradiol binding. Secondly, these tumors convert less estradiol to the weaker estrone (Englund, 1998; Otubu, 1982; Yamamoto, 1993). A third mechanism described by Bulun and colleagues (1994) involves higher levels of cytochrome P450 aromatase in leiomyomas compared with normal myocytes. This specific cytochrome isoform catalyzes the conversion of androgens to estrogen in a number of tissues.

There are a number of conditions associated with increased estrogen production that encourage leiomyoma formation. For example, the increased years of estrogen exposure found with early menarche and with an increased body mass index (BMI) are each linked with a greater risk of leiomyomas (Marshall, 1998; Wise, 2005b). Obese women produce more estrogens from increased adipose conversion of androgens to estrogen and display decreased hepatic production of sex-hormone binding globulin (Glass, 1989).

Because pregnancy is a progesterone-dominant state, it should provide an interlude from chronic estrogen exposure, and intuitively at least, should discourage leiomyoma development. In support of this, women giving birth at an early age, those with higher parity, and those with a more recent pregnancy all display lower incidences of leiomyoma formation.

In premenopausal women, estrogen and progesterone hormone treatment probably has no inductive effect on leiomyoma formation. With few exceptions, oral contraceptive combination pills either lower or have no effect on this risk (Chiaffarino, 1999; Parazzini, 1992; Ross, 1986).

Most studies evaluating the effects of hormone replacement therapy, however, show either a stimulatory or no effect on growth (Polatti, 2000; Reed, 2004). Palomba and associates (2002) evaluated the relationship between leiomyoma growth and differing doses of medroxyprogesterone acetate (MPA) in hormone replacement therapy. Because higher doses of MPA were associated with leiomyoma growth, they recommended using the lowest possible dose of MPA in these patients.

Finally, smoking alters estrogen metabolism and lowers physiologically active serum estrogen levels (Daniel, 1992; Michnovicz, 1986). This may explain why women who smoke generally have a lower risk for leiomyoma formation (Parazzini, 1992).

Progestins

The role of progesterone in leiomyoma growth is less clear, and indeed both stimulatory and inhibitory effects have been reported. For example, exogenous progestins have been shown to limit leiomyoma growth in clinical trials (Goldzieher, 1966; Tiltman, 1985). Similarly, epidemiologic studies link depot medroxyprogesterone use with a lower incidence of leiomyoma development (Lumbiganon, 1996). In contrast, other studies report a stimulatory influence of progestins on leiomyoma growth. For example, the antiprogestin, mifepristone (RU486), induces atrophy in most leiomyomas (Murphy, 1993). Moreover, in women treated with gonadotropin-releasing hormone (GnRH) agonists, leiomyomas typically decrease in size. However, if progestins are given simultaneously with agonists, there may be *increased* leiomyoma growth (Carr, 1993; Friedman, 1994).

RISK FACTORS

During the reproductive years, the incidence of this tumor increases with age. In a study by Day Baird and colleagues (2003), the cumulative incidence by age 50 years was nearly 70 percent in Caucasians and over 80 percent in African-American women. Sporadic case reports such as the one by Bekker and colleagues (2004) document their rarity in teenagers. After menopause, leiomyomas generally shrink in size, and new tumor development is uncommon. Thus, it seems that most risk or protective factors depend on circumstances that chronically alter estrogen or progesterone levels or both.

Leiomyomas are more common in African-American women compared with Caucasian, Asian, or Hispanic women. Few studies have been done to ascertain these ethnic differences (Amant, 2003; Woods, 1996). Heredity likely plays a role in susceptibility to the initial mutation involved with leiomyoma development. Family and twin studies have shown the risk of leiomyoma formation to be approximately two times greater in women with affected first-degree relatives (Sato, 2002; Vikhlyaeva, 1995).

CLASSIFICATION OF UTERINE LEIOMYOMAS

Leiomyomas are classified based on their location and direction of growth (Fig. 9-3). *Subserosal leiomyomas* originate from myocytes adjacent to the uterine serosa, and their growth is directed outward. When these are attached only by a stalk to their progenitor myometrium, they are called *pedunculated leiomyomas* . *Parasitic leiomyomas* are subserosal variants that attach themselves to nearby pelvic structures from which they derive vascular support, and then may or may not detach from the parent myometrium. *Intramural leiomyomas* are those with growth centered within the uterine walls. Finally, *submucous leiomyomas* are proximate to the endometrium and grow toward and bulge into the endometrial cavity. Only about 0.4 percent of leiomyomas develop in the cervix (Tiltman, 1998). Leiomyomas have also been found less commonly in the ovary, fallopian tube, broad ligament, vagina, and vulva.

FIGURE 9-3

Leiomyomas can be described as submucous, subserosal, intramural, or pedunculated. The borders of most leiomyomas overlap these distinct regions.

Leiomyomatosis

Extrauterine smooth muscle tumors, which are benign yet infiltrative, may develop in women with concurrent uterine leiomyomas. This condition is termed *leiomyomatosis,* and its categorization is described below. In such cases, the diagnosis of malignant metastasis from a leiomyosarcoma must be excluded.

Intravenous leiomyomatosis is a rare, benign smooth muscle tumor that invades and extends serpiginously into the uterine and other pelvic veins, vena cava, and even cardiac chambers. Although histologically benign, the tumor can be fatal as a consequence of venous obstruction or cardiac involvement (Fang, 2007; Uchida, 2004).

Benign metastasizing leiomyomas derive from morphologically benign uterine leiomyomas which disseminate hematogenously. Lesions have been found in the lungs, gastrointestinal tract, spine, and brain (Alessi, 2003). Classically, these are found in women who have a recent or distant history of pelvic surgery (Zaloudek, 2002).

Disseminated peritoneal leiomyomatosis appears as multiple small nodules on the peritoneal surfaces of the abdominal cavity or the abdominal organs or both. They are usually found in women of reproductive age, and 70 percent are associated with pregnancy or combination oral contraceptives (Robboy, 2000).

Treatments for these three benign conditions involve hysterectomy with oophorectomy, tumor debulking, and more recently, use of GnRH agonists, aromatase inhibitors, and selective estrogen receptor modulators (Bodner, 2002; Rivera, 2004; Sobiczewski, 2004).

SYMPTOMS

Most women with leiomyomas are asymptomatic. However, symptomatic patients typically complain of bleeding, pain, pressure sensation, or infertility. In general, the larger the leiomyoma, the greater the likelihood of symptoms (Cramer, 1990).

Bleeding

This is the most common symptom and usually presents as menorrhagia (Olufowobi, 2004). The pathophysiology underlying this bleeding may relate to dilatation of venules. Bulky tumors are thought to exert pressure and impinge on the uterine venous system, which causes venular dilatation within the myometrium and endometrium (Figs. 9-4 and 9-5). Accordingly, intramural and subserosal tumors have been shown to have the same propensity to cause menorrhagia as submucous ones (Wegienka, 2003).

With menses and sloughing of the functionalis layer, greater bleeding follows disruption of these dilated venules. *(From Farrer-Brown, 1970, 1971, with permission.)*

Dysregulation of local vasoactive growth factors are also thought to promote vasodilatation. When engorged venules are disrupted at the time of menstrual sloughing, bleeding from the markedly dilated venules overwhelms usual hemostatic mechanisms (Stewart, 1996).

Pelvic Discomfort and Dysmenorrhea

A sufficiently enlarged uterus can cause pressure sensation, urinary frequency, incontinence, and constipation. Rarely, leiomyomas extend laterally to compress the ureter and lead to obstruction and hydronephrosis. Although dysmenorrhea is common, in a population-based cross-sectional study, Lippman and co-workers (2003) reported that women with leiomyomas more frequently had dyspareunia or noncyclical pelvic pain than dysmenorrhea.

INFERTILITY AND PREGNANCY WASTAGE

Although the mechanisms are not clear, leiomyomas can be associated with infertility. It is estimated that 2 to 3 percent of infertility cases are due solely to leiomyomas (Buttram, 1981; Kupesic, 2002). Their putative effects include occlusion of tubal ostia and disruption of the normal uterine contractions that propel sperm or ova. Distortion of the endometrial cavity may diminish implantation and sperm transport. Importantly, leiomyomas are associated with endometrial inflammation and vascular changes that may disrupt implantation (American Society for Reproductive Medicine, 2004a; Brosens, 2003; Farhi, 1995).

There is a stronger association of subfertility with submucous leiomyomas than with tumors located elsewhere. Improved pregnancy rates following hysteroscopic resection have provided most of the indirect evidence for this link (Vercellini, 1999). In one study, Garcia and Tureck (1984) reported pregnancy rates approaching 50 percent following myomectomy in women with

submucous leiomyomas as their sole source of infertility.

The relationship between subfertility and intramural and subserosal leiomyomas that do not distort the endometrial cavity is more tenuous. A number of investigators have reported equally good in vitro fertilization success rates in women with and without leiomyomas that did not distort the endometrial cavity (Farhi, 1995; Oliveira, 2004). Others, however, have reported adverse fertility effects from even intramural and subserosal leiomyomas (Hart, 2001; Marchionni, 2004).

Both uterine leiomyoma and spontaneous miscarriage are common, and an association between these has not been shown convincingly. Indirect evidence comes from studies that cite significantly lower abortion rates following resection (Campo, 2003; Vercellini, 1999).

Other Clinical Manifestations

Less than 0. 5 percent of women with leiomyomas develop *myomatous erythrocytosis syndrome* . This may result from excessive erythropoietin production by the kidneys or by the leiomyomas themselves (Kohama, 2000; Yokoyama, 2003). In either case, red cell mass returns to normal following hysterectomy.

Leiomyomas occasionally may cause *pseudo-Meigs syndrome* . Traditionally, Meigs syndrome consists of ascites and pleural effusions that accompany benign ovarian fibromas. However, any pelvic tumor including large, cystic leiomyomas or other benign ovarian cysts can cause this. The presumed etiology stems from discordancy between the arterial supply to and the venous and lymphatic drainage from leiomyomas. Resolution of ascites and hydrothorax follows hysterectomy.

DIAGNOSIS

Leiomyomas are often detected by pelvic examination with findings of uterine enlargement, irregular contour, or both. In reproductive-aged women, uterine enlargement should prompt determination of a urine or serum β-hCG level.

Imaging

Sonography is initially done to define pelvic anatomy. The sonographic appearances of leiomyomas vary from hypo- to hyperechoic, depending on the ratio of smooth muscle to connective tissue and whether there is degeneration. Calcification and cystic degeneration create the most sonographically distinctive changes (Fig. 9-6). Calcifications appear hyperechoic and commonly rim the tumor or are randomly scattered (Kurtz, 1979). Cystic or myxoid degeneration typically fills the leiomyoma with multiple, smooth-walled, round, irregularly sized but generally small hypoechoic areas.

FIGURE 9-6

If menorrhagia, dysmenorrhea, or infertility accompanies a pelvic mass, then the endometrial cavity should be evaluated for submucous leiomyomas, endometrial polyps, congenital anomalies, or synechiae (Fig. 9-7). Accordingly, saline-infusion sonography (SIS), hysteroscopy, and hysterosalpingography (HSG) may have a role. Weinraub and associates (1996) reported use of three-dimensional SIS, however, any clear advantage over two-dimensional SIS or hysteroscopy has not been demonstrated (de Kroon, 2004).

Leiomyomas have characteristic vascular patterns that can be identified by color flow Doppler. A peripheral rim of vascularity from which a few vessels arise to penetrate into the center of the tumor is traditionally seen. Doppler imaging can be used to differentiate an extrauterine leiomyoma from other pelvic masses or a submucous leiomyoma from an endometrial polyp or adenomyosis (see Chap. 8, Transvaginal Color Doppler Sonography) (Fleischer, 2003).

Magnetic resonance (MR) imaging may be required when imaging is limited by body habitus or distorted anatomy. This tool allows more accurate assessment of the size, number, and location of leiomyomas, which may help identify appropriate patients for alternatives to hysterectomy, such as myomectomy or uterine artery embolization (see Fig. 2-25) (Zawin, 1990).

MANAGEMENT

Observation

Regardless of their size, asymptomatic leiomyomas usually can be managed expectantly by annual pelvic examination (American College of Obstetricians and Gynecologists 2001). If assessment of the adnexa is hindered by uterine size or contour, some may choose to add annual sonographic surveillance (Guarnaccia, 2001).

In the past, most preferred surgical removal of a large, asymptomatic leiomyomatous uterus because of concerns regarding increased operative morbidity and cancer risks. These have been disproven, and thus otherwise asymptomatic women with large leiomyomas can also be managed expectantly (Parker, 1994; Stovall, 1994). In addition, most infertile women with uterine leiomyomata are management expectantly. For those with symptomatic tumors, surgery should be timed closely to planned pregnancy, if possible, to limit the risk of leiomyoma recurrence.

Drug Therapy

In some women with symptomatic leiomyomas, medical therapy may be preferred (Table 9-2). In addition, because leiomyomas typically regress postmenopausally, some women choose medical treatment to relieve symptoms in anticipation of menopause. In others, medical therapy, such as GnRH agonists, are used as a preoperative adjunct to surgery.

Table 9-2 Indications for the Medical Treatment of Uterine Leiomyoma

Infertility	â€“	â€“	+

COCs = combination oral contraceptive pills; GnRH = gonadotropin-releasing hormone; NSAIDs = nonsteroidal anti-inflammatory drugs.

Nonsteroidal Anti-Inflammatory Drugs

Women with dysmenorrhea have higher endometrial levels of prostaglandins F_2 and E_2 than asymptomatic women (Willman, 1976; Ylikorkala, 1978). Accordingly, treatment of dysmenorrhea and menorrhagia associated with leiomyomas is based on the role of prostaglandins as mediators of these symptoms. A number of NSAIDs have proved effective for dysmenorrhea, yet there is not one considered to be superior (Table 10-2). Prostaglandins are also associated with menorrhagia (see Chap. 8, Nonsteroidal Anti-Inflammatory Drugs) (Willman, 1976). That said, benefits of NSAIDs for leiomyoma-related bleeding are less clear. The few studies done have had conflicting results (Anteby, 1985; Makarainen, 1996; Ylikorkala, 1986). Available data do not support their use as sole agents for leiomyoma-related menorrhagia.

Hormonal Therapy

Both combination oral contraceptive pills (COCs) and progestins have been used to induce endometrial atrophy and decrease prostaglandin production in women with leiomyomas. Friedman and Thomas (1995) studied 87 women with leiomyomas and reported that those taking low-dose COCs had significantly shorter menses and no evidence of uterine enlargement. Orsini and colleagues (2002) reported similar results.

There are conflicting results from trials of the levonorgestrel-releasing intrauterine device (Mirena, Berlex, Wayne, NJ) to treat leiomyoma-related menorrhagia. Although, Grigorieva and co-workers (2003) reported reduced blood loss and improved hematocrits in these women, Mercorio and associates (2003) did not confirm these findings.

Because of unpredictable effects of progestins on leiomyoma growth with the potential to worsen symptoms, the American Society for Reproductive Medicine (2004a) does not recommend either progestins or combination COCs for leiomyoma-related symptoms.

Androgens

Both danazol and gestrinone have been found to shrink leiomyoma volume and improve bleeding symptoms (Coutinho, 1989; De Leo, 1999). Unfortunately, their prominent side effects, which include acne and hirsutism, preclude their use as first-line agents (see Chap. 10, Androgens).

GnRH Agonists

These compounds are synthetic derivatives of the GnRH decapeptide. Amino-acid substitution makes them resistant to degradation, thereby increasing their half-life and resulting in prolonged receptor binding. They are inactive if taken orally, but intramuscular, subcutaneous, and intranasal preparations are available. A number of GnRH agonists that have been studied in clinical trials are shown in Table 9-3. There is no evidence to support the superiority of one of these regimens over the others for leiomyoma treatment (Chavez, 2001).

Table 9-3 Dosages of Gonadotropin-Releasing Hormone Agonists		
Brand Name	**Generic Name**	**Dosage**
Decapeptyl	Triptorelin	3.75 mg depot IM monthly
Lupron	Leuprolide acetate	3.75 mg depot IM monthly
Zoladex	Goserelin	3.6 mg depot SC monthly
Synarel	Nararelin	200 mg taken twice daily as one spray into one nostril in the morning and one spray into the other nostril in the evening

IM = intramuscularly; SC = subcutaneously.

These drugs shrink leiomyomas by targeting the growth effects of estrogen and progesterone. They initially stimulate receptors on pituitary gonadotropes to cause a supraphysiologic release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Also called a *flare* , this phase typically lasts 1 week. With their long-term action, however, agonists downregulate receptors in gonadotropes, thus creating desensitization to further GnRH stimulation. Correspondingly, decreased gonadotropin secretion leads to suppressed estrogen and progesterone levels 1 to 2 weeks after initial GnRH agonist administration (Broekmans, 1996). Another possible mechanism is that leiomyomas themselves may contain GnRH receptors, and agonists may directly decrease leiomyoma size (Chegini, 1996; Parker, 2007; Wiznitzer, 1988).

Results with GnRH agonist treatment include dramatic decreases in uterine and leiomyoma volume. Most women experience a mean decrease in uterine volume of 40 to 50 percent, with most shrinkage occurring during the first 3 months of therapy. Clinical benefits of reduced leiomyoma volumes include pain relief and diminished menorrhagia, usually amenorrhea. During this time, anemic women are given oral iron therapy to repair red cell mass and increase iron stores (Filicori, 1983; Friedman, 1990). Most recommend treatment for a total of 3 to 6 months. Following their discontinuance, normal menses resume in 4 to 10 weeks. Unfortunately, leiomyomas then regrow and uterine volumes regain pretreatment sizes within 3 to 4 months (Friedman, 1990). Despite regrowth, Schlaff and co-workers (1989) reported symptom relief for about 1 year in half of women given GnRH agonists.

GnRH agonists have significant costs, risks, and side effects. Side effects result from a profound drop in serum estrogen levels and include vasomotor symptoms, libido changes, and vaginal epithelium dryness and accompanying dyspareunia. Importantly, 6 months of agonist therapy can result in a 6 percent loss in trabecular bone, not all of which may be recouped following discontinuation (Scharla, 1990). As a result, these agents are not recommended for use longer than 6 months.

To obviate the severity of these side effects, several medications have been added to GnRH agonist treatment. The goal of this "add-back therapy" is to counter side effects without mitigating the effects on uterine and leiomyoma volume decrease. Mizutani and co-workers (1998) found that GnRH agonists suppress leiomyoma cell proliferation and induce cell apoptosis at the fourth week of GnRH agonist therapy. They proposed that add-back therapy be withheld until after this time threshold. Because of these and other observations, add-back therapy is typically begun 1 to 3 months following GnRH agonist initiation.

Add-back therapy traditionally includes estrogen combined with a progestin. A regimen of medroxyprogesterone acetate (MPA) 10 mg (days 16 to 25 of each cycle), combined with equine estrogen 0.625 mg (days 1 to 25), or a continuous daily regimen of MPA 2.5 mg and equine estrogen 0.625 mg may be used.

Add-back therapy with selective estrogen receptor modulators (SERMs), such as tibolone and raloxifene, has also been shown to prevent bone loss. Advantages of SERMs include the ability to begin them concurrently with GnRH agonist treatment without negating the agonist effects of leiomyoma shrinkage. Unfortunately, a high percentage of women complain of vasomotor symptoms while taking SERMs (Palomba, 1998, 2004).

Because of the limitations of GnRH agonist therapy, the American College of Obstetricians and Gynecologists (2001) currently

recommends it only as a temporizing agent in women nearing menopause or as surgical pretreatment in selected women.

Preoperatively, GnRH agonists offer several advantages. Their use decreases menorrhagia and may allow correction of anemia. Decreased uterine size as a result of treatment may allow a less-complicated or extensive surgical procedure. For example, hysterectomy or myomectomy may be performed through a smaller laparotomy incision or by vaginal hysterectomy, laparoscopy, or hysteroscopy (Crosignani, 1996; Mencaglia, 1993; Stovall, 1994). A fuller discussion of preoperative GnRH agonist use can be found in Section 41-18, Myomectomy.

GnRH Antagonists

Synthetically derived GnRH antagonists have also been studied for treatment of leiomyomas. Although their profound hypoestrogenic effects are similar to those of GnRH agonists, they avoid the initial gonadotropin flare and have a more rapid action. Studies have evaluated cetrorelix and also Nal-glu, so named because of its glutamatic acid structural substitution of the original GnRH structure. Daily subcutaneous injections induce leiomyoma shrinkage comparable with GnRH agonists (Gonzalez-Barcena, 1997; Kettel, 1993). A depot form of cetrorelix, however, did not provide adequate or consistent suppression of estrogen production or leiomyoma growth (Felberbaum, 1998).

Antiprogestins

Mifepristone, also known as RU486, is the most widely available antiprogestin for treatment of leiomyomas. It has proved effective in decreasing leiomyoma volume and clinical symptoms.

Progesterone binds to either progesterone receptor A or B (PR-A, PR-B). Mifepristone exerts its effects mainly through PR-A, which is found in leiomyomas in greater amounts than PR-B (Viville, 1997). Mifepristone diminishes leiomyoma volume by approximately half. Various doses have been used and include 5, 10, 25, or 50 mg given orally daily during 12 weeks (Eisinger, 2003; Murphy, 1993). In their review, Steinauer and colleagues (2004) found that although there was not a consistent correlation between increasing mifepristone dose and leiomyoma response, increasing duration of treatment did correlate with tumor shrinkage during 3- to 6-month trials. They also reported that mifepristone was effective in improving symptoms. Of those treated, 91 percent developed amenorrhea, 75 percent reported improved pain relief, and 70 percent had fewer pressure symptoms. In a comparison of leuprolide acetate treatment and mifepristone therapy, Reinsch and associates (1994) showed comparable decreases in uterine volume, yet mifepristone was better tolerated.

Mifepristone therapy, however, has several drawbacks. Approximately 40 percent of treated women complain of vasomotor symptoms. Antiprogestational effects expose the endometrium to unopposed estrogen, and Eisinger and associates (2003) found simple hyperplasia in 28 percent of 36 women sampled. Serum levels of hepatic transaminases become elevated in about 4 percent of women, but these return to normal after discontinuation in virtually all (Steinauer, 2004). Despite its antiglucocorticoid potential, increased serum cortisol levels are unusual with mifepristone, and if elevated they revert to normal after discontinuation (Reinsch, 1994).

Uterine Artery Embolization

This is an angiographic interventional procedure that delivers polyvinyl alcohol (PVA) microspheres or other particulate emboli into both uterine arteries. Uterine blood flow is therefore obstructed, producing ischemia and necrosis. Because vessels serving leiomyomas have a larger caliber, these microspheres are preferentially directed to the tumors, sparing the surrounding myometrium.

An angiographic catheter is placed in either femoral artery and advanced under fluoroscopic guidance to selectively catheterize both uterine arteries (Fig. 9-8). Failure to embolize both uterine arteries allows existing collateral circulation between the two uterine arteries to sustain leiomyoma blood flow and is associated with a significantly poorer outcome.

As a result of leiomyoma necrosis, there typically are significant postprocedural symptomsâ€”the *postembolization syndrome.* This usually lasts 2 to 7 days, and it is classically marked by pelvic pain and cramping, nausea and vomiting, low-grade fever, and malaise. Intensity of these symptoms varies, and pain management strategies include oral, intravenous, epidural, or patient-controlled analgesia regimens (Hovsepian, 2004).

Embolization is effective for leiomyoma-related symptoms. Pron and associates (2003) followed 538 women after UAE and found a clinical success rate of 80 percent for bleeding and pain and 91 percent for patient satisfaction. In addition, for most, UAE is associated with shorter hospital stays and quicker postoperative recovery than hysterectomy. However, rates of readmission and further treatment for bleeding are higher with UAE (Edwards, 2007; Hehenkamp, 2005; Pinto, 2003). Long-term data following UAE are limited. Broder and co-workers (2002) re-evaluated a group of these women 5 years postprocedure and reported that 27 percent had required further invasive treatment(s) for their leiomyomas. The American College of Obstetricians and Gynecologists (2004) currently recommends UAE for short-term relief of bleeding or pressure symptoms.

There are a number of complications associated with UAE. Leiomyoma tissue passage is common and likely is seen only with leiomyomas that have contact with the endometrial surface. Necrotic tissue that passes into the vagina usually can be removed in the office. Those that do not pass spontaneously or that remain firmly attached to the uterine wall may require dilatation and evacuation (Spies, 2002). Transient amenorrhea, which lasts at most a few menstrual cycles, is also commonly seen following UAE and is not typically associated with increased FSH levels or menopausal symptoms. Permanent amenorrhea, however, develops occasionally. Rarely, serious complications occur following embolization and include necrosis of surrounding tissues such as the uterus, adnexa, bladder, and soft tissues.

A number of complications have been identified in women during pregnancy subsequent to UAE. Goldberg and colleagues (2004) reported increased risks for preterm delivery and malpresentation in women who were treated by UAE when compared with pregnancies that followed laparoscopic myomectomy. Increased incidence of abnormal placentation has also been identified (Pron, 2005). Due to lack of long-term outcome data, women who desire future childbearing are not currently considered candidates for UAE (American College of Obstetricians and Gynecologists, 2004).

As discussed in Chapter 2, preliminary studies indicate that magnetic resonance imagingâ€"guided focused ultrasound (MRI-FUS) therapy is a safe and feasible, minimally invasive alternative for leiomyoma treatment (Chen, 2005; Fennessy, 2007; Stewart, 2003, 2006). It may provide short-term symptom relief with the advantage of a quicker recovery and few major adverse events. However, little information is available on the costs and comparisons with other treatments such as UAE.

Surgical Management

Bleeding and pain symptoms may improve in many women using medical treatment or UAE. However, for many, surgical treatments for leiomyomas are necessary and include hysterectomy, myomectomy, and myolysis.

Hysterectomy

Removal of the uterus is the definitive and most common surgical treatment for leiomyomas. Hysterectomy for leiomyoma can be performed vaginally, abdominally, or laparoscopically. Between 1994 and 1999, more than 3.5 million hysterectomies were performed in the United States, and almost a third were performed for the diagnosis of uterine leiomyoma (Keshavarz, 2002). In a study of 418 women undergoing hysterectomy for benign gynecologic conditions, Carlson and co-workers (1994) found hysterectomy for women with symptomatic leiomyomas resulted in satisfaction rates greater than 90 percent. There were marked improvements in pelvic pain, urinary symptoms, fatigue, psychological symptoms, and sexual dysfunction.

Removal of the ovaries is not required, and the decision to perform oophorectomy at the time of hysterectomy is made based on the usual factors (see Section 41-19, Hysterectomy). Other considerations prior to hysterectomy include uterine size and preoperative hematocrit. In some cases, preoperative GnRH agonist use may provide advantages.

Myomectomy

Resection of tumors is an option for symptomatic women who desire future childbearing or for those who decline hysterectomy. This can be performed laparoscopically, hysteroscopically, or via laparotomy incision and are described in Section 41-18, Myomectomy.

Myomectomy usually improves pain, infertility, or bleeding. For example, menorrhagia improves in approximately 70 to 80 percent of patients (Buttram, 1981; Olufowobi, 2004).

Myomectomy versus Hysterectomy

Historically, hysterectomy has been recommended for women not seeking pregnancy. Many believed that myomectomy, compared with hysterectomy, carried a greater risk for perioperative morbidity. As experience accrued, myomectomy has been shown to be effective and to carry perioperative risks comparable with hysterectomy. In a number of reports, blood loss, intraoperative injuries, and febrile morbidity were similar (Iverson, 1996; Sawin, 2000).

Disadvantageously, postoperative intra-abdominal adhesions and leiomyoma recurrence are more common after myomectomy compared with hysterectomy (Stricker, 1994). Recurrence rates following myomectomy range from 40 to 50 percent (Acien, 1996; Fedele, 1995). New leiomyoma development, however, appears diminished in women who become pregnant following myomectomy, perhaps because of protective effects of increasing parity (Candiani, 1991).

Laparoscopic Myomectomy

Laparoscopic leiomyoma resection may be performed with successful outcomes (Hurst, 2005; Mais, 1996). In one study, Seracchioli and co-workers (2000) reviewed results of 131 women following myomectomy for at least one large leiomyoma. They reported equivalent pregnancy rates with fewer transfusions, shorter hospital stays, and less febrile morbidity in women undergoing laparoscopic resection compared with laparotomy. Moreover, laparoscopic myomectomy appears to incite less adhesion formation than with laparotomy (Bulletti, 1996; Dubuisson, 2000; Takeuchi, 2002).

Limitations to a laparoscopic approach, however, include uterine size and laparoscopic surgical skills, especially suturing techniques. Most advocate a one- or two-layer suture closure of leiomyoma beds following enucleation (Seinera, 1997). In addition, several investigators have recommended limiting resection to those tumors less than 8 to 10 cm because of increased hemorrhage and operating time with larger tumors (Dubuisson, 2001; Takeuchi, 2003).

There are risks associated with laparoscopic myomectomy. Excision sites have been associated with uteroperitoneal fistula or with uterine rupture during subsequent pregnancy (Nezhat, 1996). At times, laparoscopic technique requires conversion to laparotomy due to bleeding or difficult tumor enucleation. It is unclear whether laparoscopic myomectomy is associated with greater risk of recurrence. Rossetti and co-workers (2001) found equivalent rates of leiomyoma recurrence with laparotomy or laparoscopic myomectomy, whereas Nezhat and colleagues (1998) found higher rates following laparoscopy.

Hysteroscopy

Resection of submucous leiomyomas through a hysteroscope has long-term effectiveness of 60 to 90 percent for the treatment of menorrhagia (Derman, 1991; Emanuel, 1999; Hallez, 1995). Hysteroscopic leiomyoma resection also improves fertility rates, especially when tumors are the sole cause of infertility (Fernandez, 2001; Vercellini, 1999). In their review, Donnez and Jadoul (2002) calculated an overall pregnancy rate of 45 percent following hysteroscopic tumor resection in women with leiomyoma as their sole identified source of infertility.

Endometrial Ablation

There are several tissue destructive modalities that ablate the endometrium and they are discussed in detail in Section 41-36, Endometrial Ablation Procedures. These techniques are effective for women with dysfunctional uterine bleeding, but when used as a sole technique for leiomyoma-related bleeding, the failure rate approaches 40 percent (Goldfarb, 1999; Yin, 1998). In some cases, ablation is used as an adjunct to hysteroscopic leiomyoma resection in women with menorrhagia.

Myolysis

A number of techniques are available to induce leiomyoma necrosis and shrinkage and include mono- or bipolar cautery, laser vaporization, or cryotherapy. All of these techniques are used laparoscopically and consume a great deal of operating room time, incite variable degrees of necrosis within the leiomyoma and surrounding normal myometrium, and produce significant postoperative pain. Data regarding long-term symptom relief, recurrence rates, and effects on fertility and pregnancy are lacking. Until clinical trials are done, these are currently considered experimental.

Hematometra

In this condition, menstrual outflow obstruction at the level of the cervix or higher traps blood and distends the uterus.

PATHOGENESIS

Many cases of hematometra develop at menarche when menstrual flow is obstructed by congenital anomalies (see Chap. 18, Description and Patient Presentation). In this setting, hematocolpos, that is, trapped blood that distends the vagina is also commonly associated and hematosalpinx may be seen.

A number of acquired abnormalities such as scarring and neoplasms can also obstruct menstrual flow. For example, hematometra may follow surgeries of the endometrial or endocervical canal, radiation treatment, and prolonged hypoestrogenism with atrophy. Similarly, it may develop in those with Asherman syndrome or with malignancies of the uterus or cervix.

DIAGNOSIS

Women with hematometra classically complain of cyclic, midline pain. With total obstruction, there is amenorrhea. Partial obstruction causes pain accompanied by scant dark bleeding that may have a foul odor and may not be cyclic. If secondary infection and pyometra develop, fever and tachycardia may be noted. Findings on examination include an enlarged, soft or even cystic midline uterine corpus that may be tender to palpation. Clinical findings may mimic early pregnancy, cystic degeneration of leiomyomas, leiomyosarcoma, and gestational trophoblastic disease. Thus, urine or serum β-hCG assay may helpful. In cases in which the underlying cause is unclear, endocervical and endometrial biopsy is indicated to exclude malignancy.

Sonography is the principal diagnostic tool, and imaging shows a smooth, symmetric hypoechoic enlargement of the uterine cavity. Low-level internal echoes may variably be present (Wu, 1999). A hematosalpinx is seen less commonly and is identified as hypoechoic tubular distensions lateral to a hypoechoic uterus (Sailer, 1979).

TREATMENT

For most cases of hematometra, relief of the obstruction and evacuation of blood are the goals. Cervical dilatation usually relieves the accumulation (Borten, 1984). Some have described hysteroscopy following dilatation to access blood pockets and to lyse adhesions (Cooper, 2000). Congenital abnormalities may require more extensive procedures to correct the obstruction (see Chap. 18, Diagnosis and Treatment).

Adenomyosis

Adenomyosis is characterized by uterine enlargement caused by ectopic rests of endometrium located deep within the myometrium. These rests may be scattered throughout the myometriumâ€"*diffuse adenomyosis* â€"or they may form a circumscribed nodular focal collection with a pseudocapsuleâ€"*focal adenomyosis* .

The diagnosis is usually based on histologic findings in surgical specimens, although either form may be suspected clinically. Accordingly, reported incidences in hysterectomy specimens vary depending on the histologic criteria as well as the degree of sectioning, but ranges from 20 to 60 percent (Bird, 1972; Parazzini, 1997).

PATHOPHYSIOLOGY

Anatomy

On gross examination, there typically is global uterine enlargement, but this rarely exceeds that of a 12-week pregnancy. The surface contour is smooth and regular, uterine texture is softened, and reddish myometrial discoloration is common. The grossly cut uterine surface typically appears spongy with focal areas of hemorrhage (Fig. 9-9).

The ectopic foci of glands and stroma that are found in the myometrium in adenomyosis originate from the basalis layer. Because cells from the basalis layer do not undergo the typical proliferative and secretory changes during the menstrual cycle, hemorrhage within these foci is minimal.

Pathogenesis

The most widely held theory regarding adenomyosis development describes the downward invagination of the endometrial basalis layer deeply into the myometrium. The endometrial-myometrial interface is unique from most mucosal-muscular interfaces in that it lacks an intervening submucosa. Accordingly, even in normal uteri, the endometrium commonly invades the myometrium superficially.

Mechanisms which incite deep myometrial invasion are not known but in some cases, there is myometrial weakness caused by prior pregnancy or surgery or by decreased immunologic activity at the endometrial-myometrial interface (Ferenczy, 1998; Levgur, 2000). Estrogen and progesterone likely play a role in its development and maintenance. For example, adenomyosis develops during the reproductive years and regresses after menopause. Regardless of the permissive cause, cell migration and invasion proceed, and there is degradation and reconstruction of the extracellular matrix.

An alternative theory is that adenomyosis is caused by metaplasia of pluripotent mÃ¼llerian tissue. This theory provides explanation for endometrial rests that have been identified in the rectovaginal septum, far from the uterine endometrium and myometrium (Donnez, 1995).

RISK FACTORS

Parity and age are significant risk factors for adenomyosis. Specifically, nearly 90 percent of cases are in parous women and nearly 80 percent develop in women in their forties and fifties (Lee, 1984).

Adenomyosis is associated with other pathologies that are affected by cytochrome P450 aromatase expression and higher tissue

estrogen levels. These include leiomyomas, endometriosis, and endometrial cancer (Azziz, 1989). As discussed in Chapter 10, however, endometriosis has markedly different epidemiologic characteristics and is thought to arise from another mechanism. Oral contraceptives are not associated with adenomyosis, however, adenomyosis is found more commonly in women taking the selective estrogen receptor modulator tamoxifen (Cohen, 1997; Parazzini, 1997).

SYMPTOMS

About one third of women with adenomyosis have symptoms. Their severity correlates with increasing number of ectopic foci and extent of invasion (Levgur, 2000; Nishida, 1991; Sammour, 2002). Menorrhagia and dysmenorrhea are common. Menorrhagia possibly results from increased and abnormal vascularization of the endometrial lining. Dysmenorrhea is thought to be caused by increased prostaglandin production found in adenomyotic tissues compared with normal myometrium (Koike, 1992). Perhaps 10 percent complain of dyspareunia. Because adenomyosis typically develops in older parous women in their 40s and 50s, infertility is not a common complaint (Nikkanen, 1980).

DIFFERENTIAL DIAGNOSIS

Symptoms may mimic those from leiomyomas, endometrial cancer, endometriosis, and chronic pelvic inflammatory disease. Endometrial cancer, myometrial hypertrophy, or uterine contractions may appear similar to diffuse adenomyosis on sonographic imaging. Focal adenomyosis may share sonographic characteristics of leiomyomas.

DIAGNOSIS

Cancer Antigen 125

For many years, the diagnosis of adenomyosis in most cases has been made retrospectively following hysterectomy. Serum levels of the tumor marker CA125 have been evaluated as a diagnostic tool but have not proven to be helpful. Although CA125 levels are typically elevated in women with adenomyosis, they may also be elevated in those with leiomyomas, endometriosis, pelvic infection, and pelvic malignancies.

Sonography

Because transabdominal sonography does not consistently identify the often subtle myometrial changes of adenomyosis, imaging with TVS is preferred, and MR imaging may be complimentary (Bazot, 2001; Reinhold, 1998).

In the hands of experienced sonographers, findings of diffuse adenomyosis may include: (1) the anterior or posterior myometrial wall appearing thicker than its counterpart, (2) myometrial heterogeneity, (3) small myometrial hypoechoic cysts, representing cystic glands within ectopic endometrial foci, and (4) linear striated projections extending from the endometrium into the myometrium (Reinhold, 1999).

Focal adenomyosis appears as discrete hypoechoic nodules that may be differentiated from leiomyoma by their poorly defined margins, elliptical rather than globular shape, minimal mass effect on surrounding tissues, lack of calcifications, and presence of anechoic cysts of varying diameter (Fedele, 1992; Reinhold, 1998).

Because these findings may be subtle, operator experience influences diagnostic accuracy more than with most other pelvic pathology. Moreover, the presence of other concurrent uterine disease such as leiomyoma or endometrial cancer also limits accuracy. In these settings, MR imaging has proved highly accurate for diagnosis (see Fig. 2-26).

MANAGEMENT

Medical Treatment

Conservative therapy for symptomatic adenomyosis is similar to that for primary menorrhagia or dysmenorrhea. First, NSAIDs are often given (Fraser, 1986; Marjoribanks, 2003). Combination oral contraceptives and progestin-only regimens can be used to induce endometrial atrophy and decrease endometrial prostaglandin production to improve dysmenorrhea and menorrhagia. The levonorgestrel-containing intrauterine system has also been shown to be effective for treatment of adenomyosis (Fedele, 1997).

Because adenomyosis and endometriosis share endometrial origins, some have used GnRH agonists or danazol to treat adenomyosis in a fashion similar to the treatment of endometriosis. There have been no clinical trials, however, to study this

practice.

Interventional Treatment

Hysterectomy is the definitive treatment and as with other conditions, the type of surgical procedure depends on uterine size and associated uterine or abdominopelvic pathology.

Endometrial ablation or resection using hysteroscopy has been used to successfully treat dysmenorrhea and menorrhagia caused by adenomyosis (Molnar, 1997; Wortman, 2000). However, complete eradication of deep adenomyosis is problematic and is responsible for a significant number of treatment failures. Because of this, McCausland and McCausland (1996) recommended preoperative sonography or MR imaging to identify deep lesions, which allows better patient selection. Another caveat is that any injury to the endometrial lining, including ablation, may be the initiating insult that incites endometrial tissue to grow into the myometrium, thus *causing* adenomyosis.

Uterine artery embolization (Uterine Artery Embolization) has also been used to relieve symptoms for some women, although success rates vary widely and range from 25 to 90 percent (Jha, 2003; Kim, 2004; 2007; Toh, 2003).

Myometrial Hypertrophy

In some women, especially those with high parity, there is global enlargement of the uterus but no associated underlying identifiable pathology in hysterectomy specimens (Fraser, 1987). Also known as gravid hypertrophy, this condition results from myometrial fiber enlargement and not hyperplasia or interstitial fibrosis (Traiman, 1996). One definition includes uterine weights exceeding 120 g for nulliparas and 210 g for multiparas (Zaloudek, 2002). Symptoms are uncommon but may include menstrual irregularities, and of these menorrhagia is the most frequent complaint.

Uterine or Cervical Diverticula

These rare ballooned sacculations from the uterine or cervical wall communicate with and extend out from the endometrial cavity or endocervical canal. Many develop after cesarean delivery and are thought to arise at sites of uterine dehiscence. Others are thought to be congenital anomalies developing from a localized duplication of the distal mÃ¼llerian duct on one side (Engel, 1984).

A diverticulum may serve as a passive repository for menstrual flow, with intermittent expulsion of blood producing pain and intermenstrual bleeding. In addition, these saccules may become secondarily infected (Umezaki, 2004).

Transvaginal sonography or sonohysterography are typically used to evaluate women with these symptoms. Hysterosalpingography, hysteroscopy, and MR imaging have been used to show communication to the endometrium (Erickson, 1999). Treatment includes excision of the diverticulum or hysterectomy.

OVARY

Ovarian masses are a common finding in general gynecology. Of these, neoplasms constitute a significant number, and most are benign. Ovarian neoplasms can be distinguished histologically and are grouped as *surface epithelial tumors, germ cell tumors,* and *sex cord-stromal tumors* depending on their cell type of origin (see Fig. 36-1). The types and particular characteristics of these tumors are discussed in Chapters 35 and 36.

Despite continuous improvement in diagnostic methods, it is often impossible to clinically differentiate between benign and malignant conditions. Thus, management must balance concerns of performing an operation for an innocent lesion with the risk of not removing an ovarian malignancy.

Cystic Ovarian Masses

Most benign and malignant ovarian masses are predominantly cystic. The incidence of ovarian cysts varies only slightly with patient demographics and ranges from 5 to 15 percent (Dorum, 2005; Millar, 1993; Porcu, 1994).

Histologically, they are often divided into those derived from neoplastic growth, *ovarian cystic neoplasms* , and those created by disruption of normal ovulation, *functional ovarian cysts* . Differentiation of these is not always clinically apparent using either imaging tools or tumor markers. Accordingly, ovarian cysts are often managed as a single composite clinical entity.

These cysts often require excision because of symptoms or the possibility of cancer, and consequently their economic impact is significant. In their review of indications for hospitalization in the United States, Velebil and colleagues (1995) reported that approximately 200,000 women are admitted annually for benign ovarian cysts, comprising a third of admissions for gynecologic disease.

PATHOGENESIS

The exact mechanisms leading to cyst formation are unclear. Angiogenesis is an essential component of both the follicular and luteal phases of the ovarian cycle. It also participates in various pathologic ovarian processes, including follicular cyst formation, polycystic ovarian syndrome, ovarian hyperstimulation syndrome, and benign and malignant ovarian neoplasms. There is evidence that vascular endothelial growth factor serves as a major mediator of angiogenesis, and it factors into the development of ovarian neoplasms (Abulafia, 2000; Fasciani, 2001; Yamanoto, 1997).

SYMPTOMS

Most women with ovarian cysts are asymptomatic. If symptoms develop, pain and vague pressure sensations are common. Cyclic pain with menstruation may indicate endometriosis and an associated endometrioma (see Chap. 10, Patient Symptoms). Intermittent pain may reflect early torsion, whereas acute severe pain may indicate torsion with resulting ovarian ischemia (Ovarian Remnant Syndrome). Other causes of acute pain include cyst rupture or tubo-ovarian abscess (see Chap. 3, Chronic Pelvic Inflammatory Disease). In contrast, vague pressure or achiness may be the only symptom and can result from stretching of the ovarian capsule. In advanced ovarian malignancies, women complain of increased abdominal girth and early satiety from ascites or an enlarged ovary.

In some women, evidence of hormonal disruption may be found. For example, excess estrogen production from granulosa cell stimulation may disrupt normal menstruation or initiate bleeding in prepubertal or postmenopausal patients (see Chap. 36, Clinical Findings). Similarly, virilization may result from increased androgens produced by theca cell stimulation.

DIAGNOSIS

Many ovarian cysts are asymptomatic and found incidentally on routine pelvic examination or during imaging studies for another indication. Findings may vary, but typically masses are mobile, cystic, nontender, and found lateral to the uterus.

Human Chorionic Gonadotropin

In the evaluation of adnexal pathology, serologic β-hCG testing provides valuable information. Detection of serum β-hCG may indicate ectopic pregnancy or a corpus luteum of pregnancy. Less commonly, β-hCG can also serve as a tumor marker in defining ovarian neoplasm.

Tumor Markers

Tumor markers are typically proteins that are produced by tumor cells or by the body in response to tumor cells. Several such markers have been used to identify ovarian malignancies.

Cancer antigen 125 (CA125) is an antigenic determinant on a high-molecular-weight glycoprotein. As a tumor marker, serum levels are often elevated in women with epithelial ovarian cancer (Menon, 1999). Unfortunately, CA125 is not a tumor-specific antigen, and it is elevated in up to 1 percent of healthy controls. It may also be elevated in women with nonmalignant disease such as leiomyomas, endometriosis, and salpingitis. Despite these limitations, serum CA125 determinations may be helpful and are often used in the evaluation of ovarian cysts.

Serum alpha-fetoprotein (AFP) levels may be elevated in those rare patients with an endodermal sinus tumor or embryonal cell carcinoma. Increased serum levels of β-hCG may indicate an ovarian choriocarcinoma, a mixed germ cell tumor, or embryonal cell carcinoma. Lactate dehydrogenase levels may be increased in those with dysgerminoma, whereas elevated carcinoembryonic antigen and cancer antigen 19-9 (CA 19-9) levels arise from secretions of mucinous epithelial ovarian carcinomas (Campo, 1999). A more detailed discussion of these tumor markers is found in Chapters 36, Laboratory Testing.

Imaging

Both transvaginal sonography (TVS) and transabdominal sonography (TAS) are excellent methods, and cyst size is the main determinant in selecting between the two. For lesions confined to the true pelvis, TVS has superior resolution, whereas TAS is more useful for large tumors (Marret, 2001). Characteristic findings for specific types of ovarian cysts have been described and have also been defined to discriminate malignant from benign lesions (Table 9-4) (Granberg, 1989; Minaretzis, 1994; Okugawa, 2001).

Table 9-4 Recommended Management of Ovarian Masses Found with Imaging

Type of Ovarian Mass	**Recommendation**
Simple Cyst Â± Hemorrhage	
Premenopausal woman	
• ≤3 cm diameter	Invariably functional; no additional treatment required
• >3 cm diameter	The majority are functional; TVS repeated in 6â€“8 weeks;cyst may be removed if persistent
Postmenopausal woman	
• ≤5 cm diameter	The majority are benign; CA125 measurement and repeat TVS recommended; may observe if normal CA125 levelsand no interval cyst growth
• >5 cm diameter	Ovary may be removed if persistent or symptomatic
Complex mass	
Displays any of the following features: ▪ Septation ▪ Mural nodule ▪ Irregular wall thickening ▪ Shadowing echodensity ▪ Regional, diffuse, bright echoes ▪ Hyperechoic lines and dots	Malignancy difficult to exclude unless typical features of mature cystic teratoma or endometrioma identified In postmenopausal women complex masses are removed; in premenopausal women persistent complex masses are removed
Solid or predominantly solid-appearing mass	Recommend removal

Traditional gray-scale sonography may also be augmented with color flow Doppler. Transvaginal color Doppler sonography (TV-CDS) may add information regarding the nature of the lesion, its malignant potential, and the presence of torsion (Emoto, 1997; Rosado, 1992; Wu, 1994). For assessing simple ovarian cysts and the risk of malignancy, however, TV-CDS typically adds no significant advantage compared with conventional TVS (Vuento, 1995).

Use of MR imaging for ovarian cyst evaluation has been investigated. Although its added value compared with sonography is limited in most clinical settings, MR imaging may add information in situations in which anatomy or patient habitus complicates sonographic imaging (Outwater, 1996).

MANAGEMENT

Observation

Most ovarian cysts are functional, and most spontaneously regress within 6 months of identification. High-dose oral contraceptive pills have been used by some to hasten cyst resolution, however, Turan and associates (1994) found no additional benefit to this adjunctive therapy.

For postmenopausal women with a *simple* ovarian cyst, expectant management may also be reasonable. A number of investigators have confirmed the safety of this approach when several criteria are met: (1) sonographic evidence of a thin-walled, unilocular cyst; (2) cyst diameter less than 5 cm; (3) no cyst enlargement during surveillance; and (4) normal serum CA125 levels (Menon, 1999; Nardo, 2003).

Surgical Excision

Despite efforts by investigators to classify lesions by radiologic and serologic means, there is considerable morphologic similarity among cyst types as well as between those that are malignant and benign. Accordingly, for many cases, surgical excision of the cyst serves as the definitive diagnostic tool.

Cystectomy versus Oophorectomy

The decision for one surgical technique in preference over the other is dictated by lesion size, age, and intraoperative findings. For example, in premenopausal women, smaller lesions generally require only cystectomy with preservation of reproductive function. Larger lesions may necessitate oophorectomy because of the difficulty with cyst enucleation without rupture and the greater risk of malignancy in these larger cysts. However, in postmenopausal women, oophorectomy is preferred because the risk for cancer is higher and benefits to ovarian salvage are limited (Okugawa, 2001).

Clinical findings of malignancy at the time of surgery will dictate further actions. Multiple small lesions studding the peritoneal surface, ascites, and exophytic growths extending from the ovarian capsule should prompt appropriate clinical staging and treatment for ovarian cancer as discussed in Chapter 35, Management of Early-Stage Ovarian Cancer.

Laparoscopy

The surgical approach for cyst excision is also dictated by clinical factors. Laparoscopy has many advantages, but it generally has been underused for management of ovarian cysts. Concerns of increased rates of cyst rupture with the risk for tumor spill and malignant seeding have caused many to avoid this modality. That said, several investigators have documented the safety of laparoscopic cystectomy and oophorectomy (Lin, 1995; Mais, 1995; Yuen, 1997).

Mini-Laparotomy

For small or moderately sized cysts, laparotomy incisions can usually be minimized. As a result, most who undergo mini-laparotomy can be discharged the day of surgery (Berger, 1994; Flynn, 1999). Although mini-laparotomy typically offers shorter operative times, lower rates of cyst rupture, and greater cost savings compared with laparoscopy or laparotomy, this approach can limit lysis of adhesions and inspection of peritoneal surfaces for signs of ovarian malignancy.

Laparotomy

Women with a greater potential for malignancy are best managed by laparotomy, as it provides a surgical field large enough for oophorectomy or cyst enucleation without tumor rupture or spill and for surgical staging if malignancy is found.

Cyst Aspiration

Historically, there has been hesitation to aspirate ovarian cysts because of possible intraperitoneal seeding by early stage ovarian cancer. Moreover, nondiagnostic, false-positive, and false-negative results are common (Dejmek, 2003; Martinez-Onsurbe, 2001; Moran, 1993). For these reasons, very few indications exist for this procedure.

Role of the Generalist

Ovarian cysts frequently require surgical treatment. Most of these lesions are benign and typically are removed by general gynecologists. When malignancy is present, however, formal cancer staging should accompany excision. Studies support that

optimal surgical resection and proper staging performed by gynecologic oncologists during the primary operation for ovarian cancers are major factors in long-term survival. Thus, women with pelvic masses and preoperative findings suspicious for malignancy are generally referred. The American College of Obstetricians and Gynecologists and Society of Gynecologic Oncologists (2002) have presented guidelines regarding clinical criteria that should prompt referral to a gynecologic oncologist (Table 9-5). If one or more criteria from this list or other suspicious findings are identified, referral should follow (Im, 2005).

Table 9-5 Guidelines for Referral of Newly Diagnosed Pelvic Mass to Gynecologic Oncologist

Functional Ovarian Cysts

Of the different type of ovarian cysts, functional ovarian cysts are common. They originate from follicles and are created by hormonal dysfunction related to ovulation. They are subcategorized as either *follicular cysts* or *corpus luteum cysts* based on both their pathogenesis and histologic qualities. They are not neoplasms and derive mass from accumulation of intrafollicular fluids rather than cellular proliferation. Hormonal dysfunction prior to ovulation results in expansion of the follicular antrum with serous fluid and formation of a follicular cyst. In contrast, following ovulation excessive hemorrhage may fill the corpus luteum, creating corpus luteum cysts. Although these cysts generally have similar symptoms and management, they differ in the potential hormones produced as well as histologic appearance.

RISK FACTORS

Smoking

Several epidemiologic studies have linked smoking with functional cyst development (Holt, 2005; Wyshak, 1988). Although the exact mechanism(s) by which cigarette smoking exerts its effect is not known, changes in gonadotropin secretion and ovarian function are suspected (Michnovicz, 1986; Zumoff, 1990).

Contraception

High-dose oral hormonal contraceptives suppress ovarian activity and protect against cyst development (Ory, 1974). Subsequent studies, however, have shown only modest protective effects from low-dose monophasic or low-dose triphasic contraceptives (Chiaffarino, 1998; Holt, 2003).

By contrast, there is an increased incidence of follicular cysts reported with many progestin-only contraceptives. Recall that continuous, low-dose progestins do not completely suppress ovarian function (see Chap. 5, Oral Progestins). As a result, dominant follicles may develop in response to gonadotropin secretion, yet the normal ovulatory process is frequently disrupted. Follicles fail

to rupture and follicular cysts develop. In clinical studies, cystic masses were found on bimanual pelvic examination in 2 to 9 percent of women using the progestin-only implants (Brache, 2002). Similarly, levonorgestrel-containing intrauterine devices have been associated with the development of functional ovarian cysts (Inki, 2002).

One intriguing observation is that bilateral tubal ligation has been associated with an increased risk of these cysts (de Alba, 2000; Holt, 2003). The mechanism for this is unclear.

Tamoxifen

Women treated with tamoxifen for breast cancerâ€”either pre- or postmenopausalâ€”have an increased risk for ovarian cyst formation. Most studies report rates of 15 to 30 percent compared with 7 percent cited for the general postmenopausal population (Cohen, 2003; Mourits, 1999). Premenopausal women are disparately affected, and from 30 to 80 percent of women in this age group develop cysts (Mourits, 1999; Shushan, 1996).

Most of these are believed to be functional cysts, but the exact mechanism by which tamoxifen stimulates their formation is unknown. Fortunately, the majority of these cysts resolve with time whether tamoxifen treatment is continued or discontinued (Lindahl, 1997; Shushan, 1996). If small simple cysts are found, these women should undergo sonographic surveillance. However, if clinical signs of malignancy are present (see Table 9-5), then surgical exploration is indicated and tamoxifen use is discontinued.

DIAGNOSIS AND TREATMENT

Functional cysts are managed similarly to other cystic ovarian lesions. Consequently, sonography is the imaging tool of choice for evaluation. Typically, follicular cysts are completely rounded anechoic lesions with thin, regular walls (Fig. 9-10).

Conversely, corpus luteum cysts are termed "great imitators" because of their varied sonographic characteristics (Fig. 9-11). Immediately following hemorrhage into its cavity, the cyst generally appears echogenic and mimics a solid mass. With evolution of

the clot, a lacy reticular pattern develops. As the clot hemolyzes, a distinct line often forms between the serum and retracting clot. With further retraction, the clot may appear as an intramural nodule. Imaging with transvaginal color Doppler typically displays a brightly colored ring because of their increased surrounding vascularity (Swire, 2004; Yoffe, 1991). This *ring of fire* is also common to ectopic pregnancies (see Fig. 7-7).

If asymptomatic, women with findings of functional ovarian cyst may be observed, but surgical evaluation is often required for persistent cysts.

Benign Neoplastic Ovarian Cysts

These lesions, in combination with functional ovarian cysts, comprise the majority of ovarian masses. Of benign ovarian neoplasms, serous and mucinous cystadenomas (surface epithelial neoplasia group) and mature cystic teratomas (germ cell family) are by far the most common (Pantoja, 1957b). Qualities of the surface epithelial neoplasia group are discussed further in Chapter 35, whereas mature cystic teratoma are discussed below.

OVARIAN TERATOMA

These belong to the germ cell family of ovarian neoplasms. Teratomas arise from a single germ cell, and therefore may contain any of the three germ layersâ€”ectoderm, mesoderm, or endoderm. These layers typically form tissues that are foreign to the ovary and that have a disorganized structure. As a result, teratomas usually contain a haphazard collection of tissues such as hair, fat, bone, and teeth. The term "dermoid" was later coined to describe mature cystic teratomas, because of the prevalence of dermal elements in these cysts.

Teratomas are classified as:

- Immature teratomaâ€”This neoplasm is malignant. Immature tissues from one, two, or all three germ cell layers are found and frequently coexist with mature elements. These tumors are discussed in greater detail in Chapter 36, Immature Teratomas.
- Mature teratomaâ€—This benign tumor contains mature forms of the three germ cell layers and are categorized as:

(1) Mature cystic teratomas, which develop into cystic structures and may be known by several names, including *mature cystic teratoma, benign cystic teratoma,* and *dermoid cyst;*

(2) Mature solid teratomas, which have elements formed into a solid mass;

(3) Fetiform teratomas or homunculus, which forms a doll-shape and arranges the germ cell layers with considerable normal spatial differentiation;

(4) Monodermal teratoma, which is composed either solely or predominantly of only one highly specialized tissue type. Of the monodermal teratomas, those composed dominantly of thyroid tissue are termed *struma ovarii* .

Mature Cystic Teratoma (Benign Cystic Teratoma or Dermoid Cyst)

These common tumors comprise approximately 10 to 25 percent of all ovarian neoplasms and 60 percent of all benign ovarian neoplasms (Katsube, 1982; Koonings, 1989; Peterson, 1955).

Pathology

The typically sturdy cyst walls of mature cystic teratomas give these cysts a smooth, rounded or ovoid shape and lobulation is uncommon. These cystic tumors are typically slow growing and most measure between 5 and 10 cm (Comerci, 1994; Pantoja, 1975a). They are bilateral in approximately 10 percent of cases (Caruso, 1971; Katsube, 1982; Peterson, 1955).

When sectioned, most cysts appear unilocular and typically contain one area of localized growth that protrudes into the cystic cavity. Alternatively designated as *Rokitansky protuberance, dermoid plug, dermoid process, dermoid mamilla,* or *embryonal rudiment,* this protuberance may occasionally be absent or multiple.

Microscopically, endodermal or mesodermal derivatives may be found, but ectodermal elements usually predominate. The cyst is typically lined with keratinized squamous epithelium and contains abundant sebaceous and sweat glands. Hair and fatty secretions are commonly found within (Figs. 9-12 and 9-13). The Rokitansky protuberance is usually where the most varied tissue types are found and is also a common site of malignant transformation.

Malignant transformation develops in only 1 to 3 percent of cases, typically in women older than 40, and these cancers comprise only 1 percent of all ovarian malignancies (Kelley, 1961; Koonings, 1989; Peterson, 1957). Because of the preponderance of

squamous epithelium lining these cysts, it seems logical that squamous cell carcinoma comprises 80 percent of malignant cases.

Tumor Origin

The diverse tissues found within teratomas are thought not to arise by fertilization of an egg by sperm. Instead, they are theorized to develop from genetic material contained within a single oocyte. Complete embryonic development from asexual reproductionâ€”*parthenogenesis* â€”is found in lower phylogenetic organisms. In mammals, the process falls short of normal embryogenesis, but some embryonic tissue development may occur. It appears that oocytes capable of parthenogenesis result from an arrest of oocyte development following meiosis I (Eppig, 1977; Linder, 1975). As a result, almost all mature cystic teratomas have a 46, XX karyotype.

Complications

Almost 15 percent of mature cystic teratomas undergo torsion, but cyst rupture is rare. Presumably, their thick cyst wall resists rupture compared with other ovarian neoplasms. If cysts do rupture, acute peritonitis is common, and Fielder and associates (1996) attribute peritonitis to the sebum and hair contents of these cysts. They showed the benefits of lavage to prevent peritonitis and adhesion formation. Alternatively, chronic leakage of teratoma contents can lead to a granulomatous peritonitis that may initially be visually misinterpreted as widespread malignancy (Phupong, 2004).

Risk Factors

Mature cystic teratomas are found in women from childhood to after menopause. In their review of nearly 1,000 cases, Peterson and co-workers (1955) found 91 percent of tumors in women aged 15 to 50 years with a peak incidence in those 20 to 40 years (Benjapibal, 2000; Comerci, 1994).

These tumors are frequently identified during pregnancy. Although cause and effect seems unlikely, up to 10 percent of mature cystic teratomas are diagnosed in pregnant women. These account for one fourth to one half of ovarian tumors diagnosed at that time (Sherard, 2005; Usui, 2000).

Diagnosis

Symptoms from mature cystic teratomas are similar to those of other ovarian cysts. As a result, sonography is the main imaging tool used in their identification (Fig. 9-14). As described earlier, these tumors have a wide range of consistencies, from completely cystic to completely solid. Despite these variations, mature cystic teratomasâ€”more so than most ovarian tumorsâ€”display a number of characteristic sonographic features:

- "Tip of the iceberg"â€”This sign is created by amorphous echogenic interfaces of fat, hair, and tissues in focus in the foreground that shadow and thus obscure structures behind it (Guttman, 1977).
- Fat-fluid or hair-fluid levelsâ€”A distinct linear demarcation can be seen within the cyst when serous fluid interfaces with sebum alone or sebum mixed with hair.
- Hairâ€—This frequent component of mature cystic teratomas, when intermixed with sebum, forms accentuated lines and dots that represent hair in longitudinal and transverse planes (Bronshtein, 1991).
- Rokitansky protuberanceâ€—This mural nodule found in the majority of mature teratomas has a characteristic sonographic appearance. The typically rounded protuberance ranges in size from 1 to 4 cm, is predominantly hyperechoic, and creates an acute angle with the cyst wall.

Although these findings are frequently seen in mature cystic teratomas, they may also be found in other ovarian cysts. For example, Patel and associates (1998) reported modest positive predictive values for these findings individually. However, they described values of 100 percent when two or more were found within a given lesion.

Treatment

For most women with mature cystic teratoma, surgical excision provides a definitive diagnosis, affords relief of symptoms, and prevents complications of torsion, rupture, and malignant degeneration. As with other ovarian cysts, excision may be by laparoscopic or laparotomic approach, and either cystectomy or oophorectomy can be performed. Cystectomy offers comparable clinical success to oophorectomy for women who wish to preserve fertility. Mais and co-workers (2003) identified no recurrences in women undergoing cystectomy for a mature cystic teratoma by either laparoscopy or laparotomy.

In the past, most recommended that the opposite ovary be explored because of the high frequency of bilateral lesions. Surgeons commonly bivalved, wedged, or biopsied grossly normal contralateral ovaries. With accurate sonographic imaging, these procedures are no longer indicated with a normal appearing contralateral ovary (Comerci, 1994).

Solid Ovarian Tumors

Completely solid ovarian masses typically are benign. That said, these masses should still be removed because of the inability to exclude malignancy in these tumors. Ovarian tumors may presents as a solid mass and may represent sex cord-stromal tumors, Krukenberg tumor, ovarian leiomyoma and leiomyosarcoma, carcinoid, primary lymphoma, and transition cell tumors, also called Brenner tumors.

Ovarian Remnant Syndrome

Persistent functional ovarian tissue following incomplete oophorectomy can present as a pelvic mass if ovarian pathology develops.

In symptomatic women, they most commonly cause pain and are discussed in detail in Chapter 11, Ovarian Remnant Syndrome and Ovarian Retention Syndrome (Mahdavi, 2004). Dense adhesive disease at the time of oophorectomy is the greatest risk factor, and women with a history of pelvic inflammatory disease, endometriosis, or pelvic surgery are more commonly affected (Nezhat, 2005).

TORSION OF ADNEXAL MASSES

Torsion involves the twisting of adnexal components. Most commonly, the ovary and fallopian tube rotate as a single entity around the broad ligament. Infrequently, the ovary may alone turn about its mesovarium, and rarely the fallopian tube may twist alone about the mesosalpinx (Lee, 1967). Torsion may occur with normal adnexa, but in 50 to 80 percent of cases unilateral ovarian masses are identified (Nichols, 1985; Warner, 1985).

Incidence

Adnexal torsion is most common during the reproductive years. Hibbard and colleagues (1985) found that 70 percent of cases developed in women aged 20 to 39 years. Postmenopausal women may also be affected. A disproportionate number of cases of adnexal torsion develop during pregnancy, and these compose 20 to 25 percent of all torsion cases.

Pathophysiology

Adnexal masses with increased mobility have greater torsion rates. Congenitally long ovarian ligaments create excessively mobile mesovaria or fallopian tubes and may increase the risk in even normal adnexa (Bellah, 1989; Graif, 1988). Similarly, pathologically enlarged ovaries with a diameter more than 6 cm will typically arise from the true pelvis. Without these bony confines, mobility and risk of torsion are increased. Accordingly, the highest rates of torsion are found in adnexal masses from 6 to 10 cm (Houry, 2001). Masses that are lighter relative to their radius are also at increased risk.

Two key points assist in initially maintaining blood flow to the involved adnexal structures despite twisting of their vascular pedicles. First, adnexa are supplied from the adnexal branches of both the uterine and ovarian vessels. During torsion, one of these, but not the other, may be involved. Secondly, although low-pressure veins draining the adnexa are compressed by the twisting pedicle, high-pressure arteries initially resist compression. During torsion, as a result of this continued inflow but arrested egress of blood, the adnexa become congested and edematous, but do not infarct. Because of this, it is reasonable to conservatively manage cases of early torsion. With continued stromal swelling, however, arteries may become compressed, leading to infarction and necrosis.

Symptoms

Classically, a woman with adnexal torsion complains of sharp lower abdominal. The onset is sudden and worsens intermittently over several hours. The pain usually is localized to the involved side, with radiation to the flank and thigh. Low-grade fever suggests adnexal necrosis. Nausea and vomiting frequently accompany the pain.

Diagnosis

IMAGING

Sonography plays an essential role in evaluation. Sonographic findings, however, can vary widely depending on the degree of vascular compromise, the characteristics of any associated intraovarian or intratubal pathology mass, and the presence or absence of adnexal hemorrhage. Sonographically, torsion may mimic ectopic pregnancy, tubo-ovarian abscess, hemorrhagic ovarian cyst, and endometrioma. Accordingly, rates of correct diagnosis with sonography range from 50 to 75 percent (Graif, 1984; Helvie, 1989).

Despite these limitations, specific findings associated with ovarian torsion have been described. First, the presence of multiple follicles rimming an enlarged ovary has a reported detection rate of 64 percent (Farrell, 1982; Graif, 1988). This finding reflects ovarian congestion and edema described earlier. As shown in Figure 9-15, the twisted pedicle may also give the appearance described as a bull's-eye target, a whirlpool, or a snail shell, that is, a rounded hyperechoic structure with multiple inner concentric hypoechoic broad rings (Vijayaraghavan, 2004). Transvaginal color Doppler sonography (TV-CDS) may add significant information

for clinical evaluation. Commonly, disruption of normal adnexal blood flow can be seen (Albayram, 2001). In most cases, intraovarian venous flow is absent. As torsion advances, intraovarian arterial flow may subsequently be lacking. However, despite its typical high predictive value for most cases, adnexa with incomplete or intermittent torsion may at times still display both venous and arterial flow. Thus, disruption of vascular flow is highly suggestive of torsion, but torsion should not be excluded on the basis of a normal Doppler study alone.

Computed tomography or MR imaging may be helpful in complicated cases, or in those with ambiguous clinical presentation such as that seen with incomplete or chronic torsion (Rha, 2002).

Management

Salvage of the involved adnexa, resection of any associated cyst or tumor, and possible oophoropexy are goals of treatment. Findings of adnexal necrosis or rupture with hemorrhage, however, may necessitate removal of torsed structures.

Torsion may be evaluated by laparoscopy or laparotomy techniques. Previously, when surgical exploration was performed, adnexectomy was usually done to avoid possible thrombus release upon detorsion and subsequent embolism. Evidence does not support this. McGovern and co-workers (1999) reviewed nearly 1,000 cases of torsion and found pulmonary embolism in only 0.2 percent. Of note, these cases of embolism were associated with adnexal excision and none were linked to conservative untwisting of the pedicle. In a study of 94 women with adnexal torsion, Zweizig and associates (1993) reported no increased morbidity in

women undergoing untwisting of the adnexa compared with those undergoing adnexectomy.

For these reasons, detorsion of the adnexa is generally recommended. Within minutes following untwisting, congestion is relieved, and ovarian cyanosis and volume typically diminish. For many, absence of these changes may prompt adnexal removal. A persistently black-bluish ovary, however, is not pathognomonic for necrosis, and the ovary may still recover. Cohen and associates (1999) reviewed 54 cases in which adnexa were preserved regardless of their appearance following detorsion. They reported functional integrity and successful subsequent pregnancy in almost 95 percent. Bider and colleagues (1991) observed no increased postoperative infectious morbidity in cases similarly managed. Because necrosis may still occur, conservative management necessitates postoperative vigilance for fever, leukocytosis, and peritoneal signs.

Specific ovarian lesions should be excised. Cystectomy in an ischemic, edematous ovary, however, may technically be difficult. Therefore, some authors recommend delaying cystectomy until 6 to 8 weeks after primary intervention (Rody, 2002).

Following detorsion, there is no consensus as to the management of the adnexa. As conservative management has evolved, the incidence of repeated torsion will likely increase. Unilateral or bilateral oophoropexy has been described to minimize the risk of repeat ipsilateral torsion or contralateral adnexal torsion (Djavadian, 2004; Germain, 1996).

Management during pregnancy does not differ. If the corpus luteum is removed before 10 weeks' gestation, intramuscular 17-hydroxyprogesterone caproate, 150 mg, is recommended to maintain pregnancy. If between 8 and 10 weeks, then only one injection is required immediately after surgery. If the corpus luteum is excised between 6 to 8 weeks, then two additional doses should be given 1 and 2 weeks after the first.

PARAOVARIAN MASSES

Paraovarian and Paratubal Cysts

These arise as either embryologic remnants or as true neoplasms. Most paraovarian cysts are not neoplastic, but are either distended remnants of the mesonephric ducts or mesothelial inclusion cysts (see Fig. 18-1). Extremes of size have been noted but most measure less than 3 cm (Genadry, 1977). The most common paratubal cyst is the *hydatid of Morgagni* , which is pedunculated and typically dangles from one of the fimbria (Fig. 9-16). Neoplastic paraovarian cysts are rare, and histologically resemble tumors of ovarian origin. They are usually cystadenomas or cystadenofibromas and are rarely of borderline potential or malignant (Honore, 1980; Korbin, 1998).

FIGURE 9-16

The reported incidence of para-adnexal cysts varies, but a recent autopsy series cited a rate of about 5 percent of adnexal cysts (Dorum, 2005). No certain risks have been associated with their formation, although some have reported them to be more common following in-utero exposure to diethylstilbestrol (Haney, 1986; Wise, 2005a).

Para-adnexal cysts are most commonly identified in asymptomatic women at the time of surgery or sonography for other gynecologic problems. They are generally not detected on pelvic examination. If symptoms develop, they mimic those of any other ovarian pathology such as abdominal or pelvic pain or increasing girth. They are infrequently associated with complications such as hemorrhage, rupture, or torsion (Genadry, 1977).

Transvaginal sonography is often used as the primary tool for evaluation of a symptomatic woman. Most cysts have thin, smooth walls and anechoic centers. Eccentrically located cysts may resemble hydrosalpinx. Sonography, however, has limitations in differentiating between paraovarian and ovarian pathology (Athey, 1985; Barloon, 1996). Moreover, MR imaging was not found helpful in differentiating between ovarian and paraovarian cysts (Ghossain, 2005). Thus, many women are managed similarly as for the diagnosis of ovarian cyst. When surgically managed, cystectomy, or less frequently drainage and fulguration of the cyst wall, are performed.

Paraovarian Solid Tumors

Leiomyoma is the most common solid paraovarian mass, with pathophysiology identical to those within the myometrium. Infrequently, congenital anomalies such as an accessory or supernumerary ovary or a rudimentary uterine horn may be present. Other rare paraovarian solid tumors include sarcomas, lymphoma, adenocarcinoma, pheochromocytoma, choriocarcinoma, and solid Wolfiian duct remnants.

Most paraovarian solid tumors are asymptomatic and identified on routine pelvic examination. Occasionally, there is unilateral pelvic or abdominal pain. Sonography and MR imaging are used to visualize these masses, although accurate differentiation between benign and malignant lesions is typically not possible. Thus, most solid masses are surgically removed.

FALLOPIAN TUBE PATHOLOGY

The bulk tubal pathologies involve ectopic pregnancy (see Chap 7) or the sequelae of pelvic inflammatory disease (PID) (see Chap.

3, Pelvic Inflammatory Disease). Fallopian tube neoplasms are rare (see Chap. 35, Fallopian Tube Carcinoma).

Hydrosalpinx

This chronic swelling of the fallopian tube is commonly a long-term result of PID. Accordingly, risk factors are the same as those for PID. Grossly, the fine fimbria and tubal ostia are obliterated and replaced by a smooth, clubbed end (Fig. 9-17). The ballooned, thin walls of the elongated tube are whitish and translucent, and the tube is typically distended with a clear serous fluid. Depending on the degree and location of the ipsilateral ovary, the hydrosalpinx may be adhered to it.

FIGURE 9-17

Hydrosalpinx may be found in asymptomatic women during pelvic examination or sonography done for other indications. Some women note infertility or chronic pelvic pain. The differential diagnosis mimics that for other cystic pelvic lesions discussed on Cystic Ovarian Masses. In general, no laboratory test is helpful, and serum CA125 level testing for presumed ovarian malignancy is typically negative.

Sonography has low sensitivity for detection of hydrosalpinges during infertility evaluation. However, in women with sonographic findings, there is usually a thin-walled, hypoechoic cystic structure with incomplete septa (Fig. 9-18). In some, multiple hyperechoic mural nodules measuring 2 to 3 mm arch around the inner circumference of the tube to create the *beads on a string* sign. These nodules represent fibrotic endosalpingeal folds.

FIGURE 9-18

Management varies depending on the conviction of diagnosis, desire for future fertility, and associated symptoms. In asymptomatic women who have completed childbearing, and in whom the sonographic evidence supports the diagnosis of hydrosalpinx, expectant management is typical. In those with pelvic pain, infertility, or in whom the diagnosis is uncertain, diagnostic laparoscopy is performed.

For women not wishing to preserve fertility, laparoscopic treatment may include lysis of adhesions and salpingectomy. Conversely, in women who desire fertility, surgical intervention depends on the degree of tubal damage (see Chap. 20, Correction of Anatomic Abnormalities). As the degree of tubal distortion increases, fertility rates decrease (Schlaff, 1990). In women with mild tubal disease, laparoscopic neosalpingostomy has resulted in 80-percent pregnancy rates and is a reasonable approach. In those women with severe disease, in vitro fertilization (IVF) may offer a greater chance at fertility.

Of note, women with a hydrosalpinx who undergo IVF have about half the pregnancy rate of other women (American Society for Reproductive Medicine, 2004b). One theoretical explanation is that the hydrosalpinx fluid bathes the endometrial cavity with toxic fluid that contains bacteriologic agents, debris, lymphocytes, cytokines, lymphokines, and prostaglandins. This is suggested to lower blastocyst implantation and affect embryo growth (Johnson, 2004; Strandell, 2002). This is supported by studies showing improved subsequent pregnancy, implantation, and live birth rates following resection of hydrosalpinges prior to IVF (Dechaud, 1998; Johnson, 2004; Strandell, 1999). For all of these reasons, the American Society for Reproductive Medicine (2004b) recommends such surgery prior to IVF.

Benign Neoplasms

These tumors of the fallopian tube are rare. For example, the most common benign tumor of the fallopian tube is the mesothelioma, which is found in less than 1 percent of specimens (Pauerstein, 1968). Previously termed adenomatoid tumors, these 1- to 2-cm, well-circumscribed solid nodules arise in the tubal wall (Salazar, 1972). Tubal leiomyomas are uncommon and derive from the smooth muscle of the muscularis, broad ligament, or from vessels in either location. Additionally, hemangioma,

lipoma, chondroma, adenofibroma, cystadenofibroma, angiomyolipoma, and neural tumors may rarely develop.

Tubo-Ovarian Abscess

Tubo-ovarian abscess (TOA) is usually a consequence of pelvic inflammatory disease (PID). Occasionally, however, endometritis, pyelonephritis, and pelvic malignancy may be the source. Pelvic abscesses are classically polymicrobial with predominance of anaerobic bacteria. Infrequently in the United States, TOA may follow *Actinomyces* infection complicating use of an intrauterine device (see Chap. 5, Infection), or pelvic tuberculosis may form TOAs (Chow, 2002; Fiorino, 1996).

Women with TOA most commonly present with lower abdominal pain and with unilateral or bilateral adnexal masses. Fever and leukocytosis may be absent. Abscess rupture causes severe pain with chills, fever, and progressive peritonitis. If large volumes of pus are released into the peritoneal cavity, infection may spread upward along the colonic gutters to form subphrenic abscesses that cause shoulder pain. Sonography is typically diagnostic, but surgical exploration may be required to confirm the diagnosis. Tubo-ovarian abscess is more fully discussed in Chapter 3, Sonography.

ENDOMETRIOSIS: INTRODUCTION

Endometriosis is a common benign gynecologic disorder defined as the presence of endometrial glands and stroma outside of the normal location. First identified in the mid-nineteenth century (Von Rokitansky, 1860), endometriosis is most commonly found on the pelvic peritoneum but may also be found on the ovaries, rectovaginal septum, ureter, and rarely in the bladder, pericardium, and pleura (Comiter, 2002; Giudice, 2004). Endometriosis is a hormonally dependent disease and as a result is chiefly found in reproductive-aged women. Endometrial tissue located within the myometrium is termed adenomyosis and is discussed in greater detail in Chapter 9, Adenomyosis.

The incidence of endometriosis is difficult to quantify, as women with the disease are often asymptomatic, and imaging modalities have low sensitivities for diagnosis. Women with endometriosis may be asymptomatic, subfertile, or suffer varying degrees of pelvic pain. The primary method of diagnosis is laparoscopy, with or without biopsy for histologic diagnosis (Kennedy, 2005; Marchino, 2005). Using this standard, investigators have reported the annual incidence of surgically diagnosed endometriosis to be 1.6 cases per 1,000 women aged between 15 and 49 years (Houston, 1987). In asymptomatic women, the prevalence of endometriosis ranges from 2 to 22 percent, depending on the population studied (Eskenazi, 1997; Mahmood, 1991; Moen, 1997). However, because of its link with infertility and pelvic pain, endometriosis is notably more prevalent in subpopulations of women with these complaints. In infertile women, the prevalence has been reported to be between 20 to 50 percent and in those with pelvic pain, 40 to 50 percent (Balasch, 1996; Eskenazi, 2001).

PATHOPHYSIOLOGY

Etiology

Although the definitive cause of endometriosis remains unknown, several theories with supporting evidence have been described.

RETROGRADE MENSTRUATION

The earliest and most widely accepted theory relates to retrograde menstruation through the fallopian tubes with subsequent dissemination of endometrial tissue within the peritoneal cavity (Sampson, 1927). Refluxed endometrial fragments adhere to and invade the peritoneal mesothelium and develop a blood supply, which leads to continued implant survival and growth (Giudice, 2004).

First proposed in the 1920s, this theory has gained support with the findings of greater volumes of refluxed blood and endometrial tissue in the pelves of women with endometriosis (Halme, 1984). Uterine hyperperistalsis and dysperistalsis have been noted in women with endometriosis and resulted in subsequent increased endometrial reflux (Leyendecker, 2004). Additionally, D'Hooghe (1997) demonstrated that surgical obliteration of the cervical outflow tract in baboons leads to the induction of endometriosis. Women with amenorrhea due to outflow tract obstruction similarly have a high incidence of endometriosis, which is often relieved by correction of the obstruction (Sanfilippo, 1986).

LYMPHATIC OR VASCULAR SPREAD

Evidence also supports the concept of endometriosis originating from aberrant lymphatic or vascular spread of endometrial tissue (Ueki, 1991). Findings of endometriosis in unusual locations, such as the perineum or groin, bolster this theory (Mitchell, 1991; Pollack, 1990). The retroperitoneal region has abundant lymphatic circulation. Thus, cases in which no peritoneal implants are found, but solely isolated retroperitoneal lesions are noted, suggest lymphatic spread (Moore, 1988). Additionally, the tendency of

endometrial adenocarcinoma to spread via the lymphatic route indicates the ease at which endometrium can be transported by this route (McMeekin, 2003). Although this theory remains attractive, few studies have experimentally evaluated this form of endometriosis transmission.

COELOMIC METAPLASIA

The theory of coelomic metaplasia suggests that the parietal peritoneum is a pluripotential tissue that can undergo metaplastic transformation to tissue histologically indistinguishable from normal endometrium. Because the ovary and the progenitor of the endometrium, the mÃ¼llerian ducts, are both derived from coelomic epithelium, metaplasia may explain the development of ovarian endometriosis. In addition, the theory has been extended to include the peritoneum because of the proliferative and differentiation potential of the peritoneal mesothelium. This theory is attractive in instances of endometriosis in the absence of menstruation, such as in premenarchal and postmenopausal women, and in males treated with estrogen and orchiectomy for prostatic carcinoma (Dictor, 1988; Pinkert, 1979). However, the absence of endometriosis in other tissues derived from coelomic epithelium argues against this theory.

INDUCTION THEORY

Finally, the induction theory proposes that some hormonal or biologic factor(s) may induce the differentiation of undifferentiated cells into endometrial tissue (Vinatier, 2001). These substances may be exogenous or released directly from the endometrium (Bontis, 1997). In vitro studies have demonstrated the potential for ovarian surface epithelium, in response to estrogens, to undergo transformation to form endometriotic lesions (Matsuura, 1999). Although many putative factors have been identified, their propensity to cause endometriosis in some women but not in others demonstrates the still unidentified etiology of this disease.

Hormonal Dependence

One factor that has been definitively established as having a causative role in the development of endometriosis is estrogen (Gurates, 2003). Although most estrogen in women is produced directly by the ovaries, numerous peripheral tissues are also known to create estrogens through aromatization of ovarian and adrenal androgens. Endometriotic implants have been shown to express aromatase and 17β-hydroxysteroid dehydrogenase type 1, the enzymes responsible for conversion of androstenedione to estrone and of estrone to estradiol, respectively. Implants, however, are deficient in 17β-hydroxysteroid dehydrogenase type 2, which inactivates estrogen (Kitawaki, 1997; Zeitoun, 1998). This enzymatic combination ensures that implants will be exposed to an estrogenic environment. Furthermore, the locally produced estrogens within endometriotic lesions may exert their biologic effect within the same tissue or cell in which they are produced, a process referred to as *intracrinology* .

In contrast, normal endometrium does not express aromatase and has elevated levels of 17β-hydroxysteroid dehydrogenase type 2 in response to progesterone, which ensures that estrogenic effects are attenuated in response to progesterone (Satyaswaroop, 1982). As a result, progesterone antagonizes the estrogen effects in normal endometrium during the luteal phase of the menstrual cycle. Endometriosis, however, manifests a relative progesterone-resistant state, which prevents attenuation of the estrogen stimulation in this tissue (Attia, 2000).

Prostaglandin E_2 (PGE_2) is the most potent inducer of aromatase activity in endometrial stromal cells, acting through the prostaglandin EP_2 receptor subtype (Noble, 1997; Zeitoun, 1999). Estradiol produced in response to the increased aromatase activity subsequently augments PGE_2 production by stimulating cyclooxygenase type 2 (COX-2) enzyme in uterine endothelial cells (Fig. 10-1) (Bulun, 2002; Gurates, 2003). This creates a positive feedback loop and potentiates the estrogenic effects on proliferation of endometriosis. This concept of locally produced estrogens and intracrine estrogen action in endometriosis serves as the basis for pharmacologic inhibition of aromatase activity in cases of endometriosis that are refractory to standard therapy.

Activation of COX-2 in endometrial stromal cells results in upregulation of PGE_2 , a potent stimulator of aromatase in endometrial stromal cells. Aromatase activity results in intracellular aromatization of androgens to increase intracellular estradiol via an intracrine mechanism. a = androgen; E_2 = estradiol; COX-2 = cyclooxygenase 2; PGE_2 = prostaglandin E2; IL-1β = interleukin 1β; VEGF = vascular endothelial growth factor.

Role of the Immune System

Although most women experience retrograde menstruation, which may play a role in the seeding and establishment of implants, few develop endometriosis. Menstrual tissue and endometrium that is refluxed into the peritoneal cavity is usually cleared by immune cells such as macrophages, natural killer (NK) cells, and lymphocytes. For this reason, immune system dysfunction is one likely mechanism for the genesis of endometriosis in the presence of retrograde menstruation (Seli, 2003). Impaired cellular and humoral immunity and altered growth factor and cytokine signaling have each been identified in endometriotic tissues.

Macrophages act as scavenger cells in various tissues and increased numbers have been found in the peritoneal cavity of women with endometriosis (Haney, 1981; Olive, 1985b). Although this increased population might logically act to suppress endometrial proliferation, macrophages in these women, however, have a stimulatory effect on endometriotic tissue. In one study, circulating monocytes obtained from women with endometriosis enhanced the in vitro proliferation of cultured endometrial cells, whereas the monocytes from women without endometriosis had the opposite effect (Braun, 1994). It appears therefore that impaired function, and not population size, of macrophages allows endometriotic tissue proliferation.

Natural killer cells are immune cells that have cytotoxic activity against foreign cells. Although the number of NK cells is unaltered in the peritoneal fluid of women with endometriosis, decreased NK cell cytotoxicity against endometrium has been demonstrated

(Ho, 1995; Wilson, 1994). Specifically, the peritoneal fluid from women with endometriosis has been found to suppress NK cell activity, suggesting that soluble factors may play a role in NK cell suppression (Oosterlynck, 1993).

Cellular immunity may also be disordered in women with endometriosis, and T lymphocytes are implicated. For example, in women with endometriosis compared with unaffected women, total lymphocyte numbers or helper/suppressor subpopulation ratios do not differ in peripheral blood, but peritoneal fluid lymphocyte numbers are increased (Steele, 1984). Also, the cytotoxic activity of T lymphocytes against autologous endometrium in affected women is impaired (Gleicher, 1984).

Humoral immunity has also been shown to be altered in affected women and is suggested to play a role in the development of endometriosis. Endometrial antibodies of the IgG class are more frequently detected in the serum of women with endometriosis (Odukoya, 1995). One study also identified IgG and IgA autoantibodies against endometrial and ovarian tissues in the sera and in cervical and vaginal secretions of affected women (Mathur, 1982). These results suggest that endometriosis may be, in part, an autoimmune disease. This may explain some of the factors influencing lower pregnancy and in vitro fertilization (IVF) implantation rates in women with endometriosis (Dmowski, 1995).

Cytokines are small, soluble immune factors involved in paracrine and autocrine signaling of other immune cells. Numerous cytokines, especially interleukins, have been implicated in the pathogenesis of endometriosis. Increased levels of interleukin-1β (IL-1β) have been identified in the endometrial fluid of those with endometriosis (Mori, 1991). Moreover, IL-6 has been shown to be increased in endometrial stromal cells of affected women (Tseng, 1996). Accordingly, IL-6 serum levels greater than 2 pg/mL and tumor necrosis factor-α (TNF-α) peritoneal fluid levels more than 15 pg/mL may be used to discriminate between those with or without endometriosis (Bedaiwy, 2002). Similarly, IL-8 peritoneal fluid levels are elevated in affected individuals and stimulate proliferation of endometrial stromal cells (Arici, 1996; Arici, 1998; Ryan, 1995).

Other noninterleukin cytokines and growth factors are associated with the pathogenesis of endometriosis. For example, both monocyte chemoattractant protein-1 (MCP-1) and RANTES (regulated on activation, normal T-cell expressed and secreted) are chemoattractant for monocytes. Levels of these cytokines are increased in the peritoneal fluid of those with endometriosis and positively correlate with disease severity (Arici, 1997; Khorram, 1993). In addition, vascular endothelial growth factor (VEGF) is an angiogenic growth factor, which is upregulated by estradiol in endometrial stromal cells and peritoneal fluid macrophages. Levels of this factor are increased in the peritoneal fluid of affected women (McLaren, 1996). Although the exact role of these cytokines is not clear, perturbations in their expression and activity further support an immunologic role in the pathogenesis of endometriosis.

RISK FACTORS

Familial Clustering

There is evidence of a familial inheritance pattern for endometriosis. Although no apparent mendelian genetics inheritance pattern has been identified, the increased incidence in first-degree relatives suggests a polygenic/multifactorial inheritance pattern. For example in a genetic study of women with endometriosis, Simpson and his colleagues (1980) noted that 5.9 percent of female siblings and 8.1 percent of the mothers of affected women had endometriosis compared with 1 percent of the husband's female first-degree relatives. Further research has revealed that women with endometriosis and an affected first-degree relative were more likely to have severe endometriosis (61%) than women without an affected first-degree relative (24 percent) (Malinak, 1980). Moreover, Stefansson and his associates (2002), in their analysis of a large population-based study in Iceland, demonstrated a higher kinship coefficient in women with endometriosis compared with matched controls. In this study, the risk ratios were 5.2 for sisters and 1.56 for cousins. Studies have also demonstrated concordance for endometriosis in monozygotic twin-pairs, suggesting a familial/genetic basis (Hadfield, 1997; Treloar, 1999).

Genetic Mutations and Polymorphisms

Rates of familial clustering noted above suggest polygenic inheritance and several candidate genes have been investigated. Two approaches to identify genes involved with endometriosis include sibling-pair linkage analysis and high-throughput analysis of gene expression patterns using microarray technology.

The largest study to date, examining over 1,000 affected sister-pair families, has identified a region on chromosome 10q26 that

demonstrates significant linkage in these sisters affected with endometriosis (Treloar, 2005). This study also revealed a smaller linkage on chromosome 20p13. Two candidate genes within or near this locus have been identified. One such gene is *EMX2* , a transcription factor necessary for reproductive tract development. It has been shown to be aberrantly expressed in the endometrium of women with endometriosis (Daftary, 2004). The second gene is *PTEN* , a tumor suppressor gene implicated in the malignant transformation of ovarian endometriosis (Bischoff, 2000). Studies are currently underway to further determine the role of these genes in endometriosis.

Microarray technology has been used to analyze differences in gene expression in eutopic endometrium (endometrium found normally lining the endometrial cavity) from women without endometriosis compared with that from women with endometriosis (Kao, 2003). Researchers found that several genes were differentially regulated in the eutopic endometrium in women with endometriosis. These include those coding for interleukin 15, glycodelin, Dickkopf-1, semaphorin E, aromatase, progesterone receptor, and various angiogenic factors. Although some of these genes have previously been shown to play a role in endometriosis, others have not been implicated until recently, and their role remains to be elucidated.

Several other genes have been identified, through genetic mutations, polymorphisms, or differential gene expression, to be associated with endometriosis. Although investigations have demonstrated polymorphisms of these genes occur with greater frequency in women suffering with endometriosis, their role in disease causation has not been determined. A more thorough review of candidate genes in the epidemiology of endometriosis can be found at the website http://www.well.ox.ac.uk/~krinaz/genepi_endo.htm .

Anatomic Defects

Reproductive outflow tract obstruction can predispose to development of endometriosis, likely through exacerbation of retrograde menstruation (Breech, 1999). Accordingly, endometriosis has been identified in women with noncommunicating uterine horn, imperforate hymen, and transverse vaginal septum (see Chap. 18, Transverse Vaginal Septum) (Schattman, 1995). Because of this association, diagnostic laparoscopy to identify and treat endometriosis is suggested at the time of corrective surgery for many of these anomalies. Repair of such anatomic defects is thought to decrease the risk of developing endometriosis (Joki-Erkkila, 2003; Rock, 1982).

Environmental Toxins

There have been numerous studies suggesting that exposure to environmental toxins may play a role in the development of endometriosis. The toxins most commonly implicated are 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and other dioxin-like compounds (Rier, 2003). In binding, TCDD activates the aryl hydrocarbon receptor. This receptor functions as a basic transcription factor, and similarly to the steroid hormone receptor family of proteins, leads to the transcription of various genes. As a result, TCDD and other dioxin-like compounds may stimulate endometriosis through increases in interleukin levels, activation of cytochrome P-450 enzymes such as aromatase, and alterations in tissue remodeling. Moreover, TCDD in conjunction with estrogen appears to stimulate endometriosis formation, and TCDD appears to block the progesterone-induced regression of endometriosis (Rier, 2003).

In the environment, TCDD and dioxin-like compounds are waste by-products of industrial processing. Ingestion of contaminated foods or accidental contact is the most common method of exposure. Although endometriosis and TCDD were initially linked in primates, human studies also note a higher prevalence of endometriosis in women with high breast milk dioxin concentrations (Koninckx, 1994; Rier, 1993). In addition, subsequent studies have demonstrated higher serum dioxin levels in infertile women with endometriosis compared with those in infertile controls (Mayani, 1997).

CLASSIFICATION AND LOCATION OF ENDOMETRIOSIS

Classification System

The primary method of endometriosis diagnosis is visualization of endometriotic lesions by laparoscopy, with or without histologic confirmation. Since the extent of endometriosis can vary widely between individuals, attempts have been made to develop a standardized classification to objectively assess the extent of endometriosis. The initial classification system attempted to provide a

scoring system to describe the pathologic extent of disease. Initially created by the American Fertility Society (AFS) 1979, which has been subsequently renamed the American Society for Reproductive Medicine (ASRM), this classification system was subsequently revised by the AFS (American Fertility Society, 1985). This revision allowed for a three-dimensional view of endometriosis and differentiated between superficial and invasive disease. Unfortunately, studies revealed that both of these classification systems did not provide any prognostic information with respect to subsequent fertility or severity of pelvic pain (Guzick, 1982, 1997). For example, one study has suggested that pain correlates with depth of invasion, which is not a significant factor in the scoring system (Koninckx, 1991).

In 1996, in an attempt to further correlate surgical findings with clinical outcomes, the ASRM further revised the endometriosis classification system (American Society of Reproductive Medicine, 1997). In this system, endometriosis is classified as stage I (minimal), stage II (mild), stage III (moderate), and stage IV (severe) (Fig. 10-2). Although there was no change in the staging system from the 1985 classification, the revised 1996 classification provided for description of endometriotic lesion morphology as white, red, or black. This modification was prompted by studies demonstrating that some biochemical activities within implants and possibly disease prognosis can be predicted by implant morphology (Vernon, 1986).

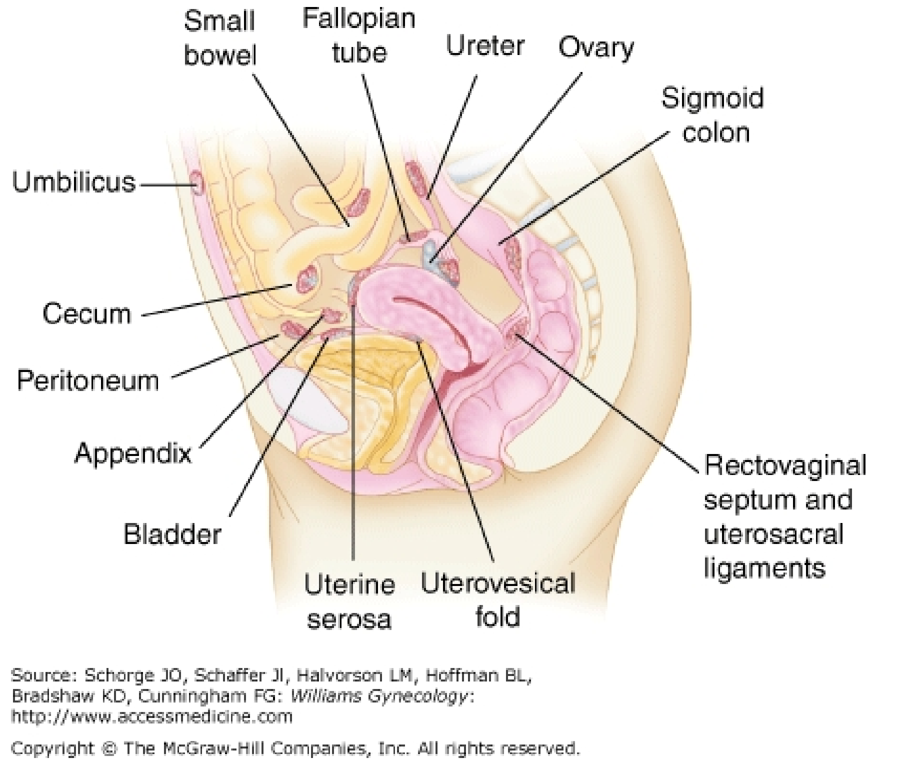
Anatomic Sites

Endometriosis may develop anywhere within the pelvis and on other extrapelvic peritoneal surfaces. Most commonly, endometriosis is found in the dependent areas of the pelvis. The ovary, pelvic peritoneum, anterior and posterior cul-de-sac, and uterosacral ligaments are frequently involved (Fig. 10-3). Additionally, the rectovaginal septum, ureter, and rarely the bladder, pericardium, surgical scars, and pleura may be affected. One pathologic review revealed that endometriosis has been identified on all organs except the spleen (Markham, 1989). Rare sites of endometriosis may present with atypical cyclic symptoms. For example, women with urinary tract endometriosis may describe cyclic irritative voiding symptoms and hematuria; those with rectosigmoid involvement may note cyclic rectal bleeding; and pleural lesions have been associated with menstrual pneumothorax or hemoptysis (Price, 1996; Roberts, 2003; Ryu, 2007; Sciume, 2004).

FIGURE 10-3



Common locations of endometriosis within the abdomen and pelvis. *(Redrawn after Olive, 2005.)*

Ovarian endometriomas are a common manifestation of endometriosis. These smooth-walled, dark-brown ovarian cysts are filled with a chocolate-appearing fluid and may be unilocular or when larger, multilocular. Ovarian endometriomas are thought to form through invagination of ovarian cortex and subsequent incorporation of menstrual debris that had been adherent to the ovarian surface (Hughesdon, 1957). Another theory has suggested that endometriomas develop as a result of coelomic metaplasia of invaginated epithelial inclusions (Nisolle, 1997).

PATIENT SYMPTOMS

Although women with endometriosis may be asymptomatic, symptoms are common and typically include chronic pelvic pain and infertility. As previously stated, the current ASRM classification of endometriosis, which describes the extent of disease bulk, poorly predicts symptoms. Thus clinically, women with extensive disease (stage IV) may note few complaints, whereas those with minimal disease (stage I) may have significant pain or subfertility or both.

Pain

Endometriosis is a common cause of pelvic pain, which in affected women can vary greatly and may be cyclic or chronic (Mathias, 1996). The underlying cause of this pain is unclear, but proinflammatory cytokines and prostaglandins released by endometriotic implants into the peritoneal fluid may be one source (Giudice, 2004). Additionally, there is also evidence to suggest that pain from endometriosis correlates with depth of invasion and that the site of pain may indicate lesion location (Chapron, 2003; Koninckx, 1991). Recent data suggest that endometriosis pain may result from neuronal invasion of endometriotic implants that subsequently develop a sensory and sympathetic nerve supply, which may undergo central sensitization (see Chapter 11). (Berkley, 2005). This leads to persistent hyperexcitability of the neurons and subsequent persistent pain, despite surgical excision. Whatever the cause, clinically women with endometriosis experience different manifestations of pain.

DYSMENORRHEA

Cyclic pain with menstruation is noted commonly in women with endometriosis. Typically, endometriosis-associated dysmenorrhea precedes menses by 24 to 48 hours and is less responsive to nonsteroidal anti-inflammatory drugs (NSAIDs) and combination oral contraceptives (COCs). This pain is thought to be more severe in comparison with primary dysmenorrhea, and Cramer and associates (1986) demonstrated a positive correlation between the severity of dysmenorrhea and the risk of endometriosis. Furthermore, deeply infiltrating endometriosis, that is, disease that extends >5 mm under the peritoneal surface, also appears to have positive correlation to the severity of dysmenorrhea (Chapron, 2003).

DYSPAREUNIA

Endometriosis-associated dyspareunia is most often related to rectovaginal septum or uterosacral ligament disease, and is less commonly associated with ovarian involvement (Murphy, 2002; Vercellini, 1996b). During intercourse, tension on diseased uterosacral ligaments may be the trigger of this pain (Fauconnier, 2002). Although some women with endometriosis may describe a history of dyspareunia since coitarche, endometriosis-associated dyspareunia is suspected if pain develops after years of pain-free intercourse (Ferrero, 2005). The degree of discomfort, however, appears to be independent of disease severity (Fedele, 1992).

DYSURIA

Although less frequent symptoms of endometriosis, bladder complaints of painful urination as well as cyclic urinary frequency and urgency may be noted in affected women. Endometriosis may be suspected if these symptoms are concurrent with negative urine cultures (Vercellini, 1996a).

DEFECATORY PAIN

Painful defecation develops less commonly than the other manifestations of pelvic pain and typically reflects rectosigmoid involvement with endometriotic implants (Azzena, 1998). Symptoms may be chronic or cyclic, and they may be associated with constipation, diarrhea, or cyclic hematochezia (Remorgida, 2007).

NONCYCLICAL PELVIC PAIN

Chronic pelvic pain is the most common symptom associated with endometriosis. Approximately 40 to 60 percent of women with chronic pelvic pain are found to have endometriosis at the time of laparoscopy (Eskenazi, 1997). Some studies have demonstrated a correlation of pain severity with advanced stage disease, whereas other studies have not (Fedele, 1992; Muzii, 1997).

The focus of chronic pain may vary from woman to woman. If the rectovaginal septum or uterosacral ligaments are involved with disease, pain may radiate to the rectum or lower back. Alternatively, pain radiating down the leg and causing cyclic sciatica may reflect posterior peritoneal endometriosis or direct sciatic nerve involvement (Possover, 2007; Vercellini, 2003a; Vilos, 2002).

Infertility

The incidence of endometriosis in women with subfertility is 20 to 30 percent (Waller, 1993). In addition, although there is wide variability reported, patients with infertility appear to have a greater incidence of endometriosis than fertile controls (13 to 33 percent versus 4 to 8 percent) (D'Hooghe, 2003; Strathy, 1982). Furthermore, Matorras and colleagues (2001) noted an increased prevalence of more severe stages of endometriosis in women with infertility. This may result from adhesions which are caused by endometriosis and impair normal oocyte pick-up and transport by the fallopian tube. Beyond mechanical impairment of ovulation and fertilization, more subtle defects also appear to be involved in the pathogenesis of infertility in women with endometriosis. Such defects include perturbations in ovarian and immune function as well as implantation.

MINIMAL OR MILD DISEASE

Although evidence from animal studies suggest that severe forms of endometriosis are associated with infertility, support for an association and causation of infertility by milder forms of endometriosis is less abundant (D'Hooghe, 1996; Schenken, 1980). Primate studies have shown that surgically-induced endometriosis resulted in a 35-percent pregnancy rate in animals with minimal endometriosis, a 12 percent rate with advanced endometriosis, and no pregnancies if ovarian adhesions were present. These rates compared poorly with a 42-percent pregnancy rate in control animals (Schenken, 1984).

Human studies demonstrating a causation of subfertility by endometriosis are lacking, but an association is suggested by the

differing prevalence of endometriosis between infertile patients and fertile women.

Evaluating women with minimal disease, Rodriguez-Escudero and colleagues (1988) reported that women with minimal endometriosis had a monthly fecundity rate of 6 percent and a 12-month cumulative pregnancy rate of 47 percent. Although this is much lower than normal fertile women, participation bias likely exists in such studies. Furthermore, a prospective cohort study demonstrated that women with minimal or mild endometriosis had a similar fecundity compared with those with unexplained infertility. Well-designed, prospective randomized controlled trials (RCTs) have found conflicting evidence as to whether surgical treatment of endometriosis improves fecundity rates and cumulative pregnancy rates in these women. One of these studies demonstrated improved fertility, but a trial with fewer women noted no improvement (Marcoux, 1997; Parazzini, 1999).

MODERATE OR SEVERE DISEASE

In moderate to severe endometriosis (stage III to IV), tubal and ovarian architecture are often distorted. As a result, impaired fertility would be expected. Unfortunately, few studies report fecundity rates in women with severe endometriosis. One investigation comparing mild, moderate, and severe endometriosis revealed a monthly fecundity rate of 8.7 percent in those with mild disease, 3.2 percent with moderate disease, and no pregnancies with severe disease (Olive, 1985a). There are no well-designed studies examining the effectiveness of surgical therapy in patients with severe endometriosis, but cumulative pregnancy rates have reached 30 percent after surgical excision (Adamson, 1993; Osuga, 2002). This rate appears to be greater than that of women who undergo expectant management.

FOLLICULOGENESIS AND EMBRYOGENESIS EFFECTS

Some researchers have suggested that folliculogenesis is impaired in women with endometriosis. Embryo development and quality in women with endometriosis undergoing IVF was compared with that of embryos originating from women with tubal factor infertility (Pellicer, 1995). There were significantly fewer blastomeres per embryo and a significantly greater rate of embryonic developmental arrest in the endometriosis group. This suggests a possible decreased developmental competence of oocytes originating from the ovaries of women with endometriosis. Another investigation found that oocyte number may be decreased in women with endometriosis (Suzuki, 2005). In addition, researchers have attempted to determine if the follicular environment is different in women with endometriosis. Specifically, studies demonstrating qualitative and quantitative changes in steroidogenesis, however, have found conflicting results (Garrido, 2002; Harlow, 1996; Pellicer, 1998). Apoptosis is another attractive theory for decreased oocyte competence in women with endometriosis, but well-designed studies are lacking.

ENDOMETRICAL CHANGES

Abnormalities in endometrial development in women with endometriosis support the possibility that implantation defects may be responsible for subfertility associated with endometriosis. For example, researchers have revealed abnormalities in gene expression profiles in the eutopic endometrium from women with endometriosis compared with that from women without endometriosis (Kao, 2003). Specifically, deficient $\alpha_v \beta_3$ integrin expression in the peri-implantation endometrium of women with endometriosis has been demonstrated, and this may be associated with decreased uterine receptivity (Lessey, 1994). The role of apoptosis on peri-implantation endometrium is another area of study that still remains largely unexplored.

OTHER FACTORS

Abnormalities in inflammation and cytokine activity in women with endometriosis may play a role in endometriosis-associated infertility. Sperm function may be affected in women with endometriosis. Studies have demonstrated increased phagocytosis of spermatozoa by macrophages from women with endometriosis (Haney, 1981; Muscato, 1982). Moreover, sperm binding to the zona pellucida appears to be adversely affected (Qiao, 1998). However, investigations of the effects of endometriosis on sperm motility and the acrosome reaction reveal conflicting results (Bielfeld, 1993; Curtis, 1993; Tasdemir, 1995).

Intestinal Obstruction

Endometriosis may involve the small bowel, cecum, appendix, or rectosigmoid colon and lead to intestinal obstruction in some cases (Cameron, 1995; Varras, 2002; Wickramasekera, 1999). Although endometriosis of the gastrointestinal tract is usually confined to the subserosa and muscularis propria, more severe cases may involve the bowel wall transmurally and lead to a clinical and radiologic picture consistent with malignancy (Decker, 2004). Accurate preoperative diagnosis and management are difficult

due to the atypical presentation. Laparoscopy typically provides the definitive diagnosis. Treatment is often surgical, with resection and primary anastomosis of the affected intestinal segment. In women without obstructing symptoms, however, conservative management with hormonal therapy may be considered.

DIFFERENTIAL DIAGNOSIS

The symptoms of endometriosis are nonspecific and may mimic many disease processes. Because endometriosis is a surgical diagnosis, several other diagnoses may be considered prior to surgical exploration (Table 10-1).

DIAGNOSIS

Physical Examination

VISUAL INSPECTION

For the most part, endometriosis is a disease confined to the pelvis. Accordingly, there are often no abnormalities on visual inspection. Some exceptions include endometriosis within an episiotomy scar or surgical scar, most often within a Pfannenstiel incision (Fig. 10-4) (Koger, 1993; Zhu, 2002). Rarely, endometriosis may develop spontaneously within the perineum or perianal

region (Watanabe, 2003).

SPECULUM EXAMINATION

Examination of the vagina and cervix by speculum examination often reveals no signs of endometriosis. Occasionally, bluish or red powder-burn lesions may be seen on the cervix or the posterior fornix of the vagina. These lesions may be tender or bleed with contact. One recent study found that speculum examination displayed endometriosis in 14 percent of patients diagnosed with deeply infiltrating endometriosis (Chapron, 2002).

BIMANUAL EXAMINATION

Pelvic organ palpation often reveals anatomic abnormalities suggestive of endometriosis. Uterosacral ligament nodularity and tenderness may reflect active disease or scarring along the ligament. In addition, an enlarged cystic adnexal mass may represent an ovarian endometrioma, which may be mobile or adherent to other pelvic structures. Bimanual examination may reveal a retroverted, fixed, tender uterus, or a firm, fixed posterior cul-de-sac.

Although pelvic organ palpation may assist in the diagnosis, the sensitivity and specificity of focal pelvic tenderness in detecting endometriosis displays wide variation and ranges from 36 to 90 percent and 32 to 92 percent, respectively (Chapron, 2002;

Eskenazi, 2001; Koninckx, 1996; Ripps, 1992). For example, Chapron and co-workers (2002) palpated a painful nodule in 43 percent of patients with deeply infiltrating endometriosis. In another study of 91 women with chronic pelvic pain and surgically confirmed endometriosis, the bimanual examination was normal 47 percent of the time (Nezhat, 1994). One study suggested that pelvic nodularities secondary to endometriosis may be more easily detected by bimanual examination during menses (Koninckx, 1996).

Laboratory Testing

To exclude other causes of pelvic pain, laboratory investigations are often undertaken. Initially, a complete blood count (CBC), urinalysis and urine cultures, vaginal cultures, and cervical swabs may be obtained to exclude infections or sexually transmitted infections that may cause pelvic inflammatory disease (see Chap. 3, Pelvic Inflammatory Disease).

SERUM CA125

Numerous serum markers have been studied as possible adjuncts in the diagnosis of endometriosis. No serum marker has been studied in greater detail than CA125 (cancer antigen 125). Found as an antigenic determinant on a glycoprotein, CA125 has been identified in several adult tissues such as the epithelium of the fallopian tubes, the endometrium, the endocervix, the pleura, and the peritoneum (see Chap. 35, Laboratory Testing). Recognized by monoclonal antibody assays, elevated CA125 levels have been shown to positively correlate with the severity of endometriosis (Hornstein, 1995a). Unfortunately, although demonstrating adequate specificity, the assay has poor sensitivity in detecting mild endometriosis. A meta-analysis of studies evaluating CA125 in the diagnosis of endometriosis revealed a sensitivity of only 28 percent and a specificity of 90 percent (Mol, 1998). This marker appeared to be a better test in diagnosing stage III and IV endometriosis. Although the role of this test in clinical practice is uncertain, it may be useful in the presence of a sonographically detected ovarian cyst suggestive of an endometrioma.

OTHER SERUM MARKERS

Cancer antigen 19-9 (CA 19-9), another antigenic glycoprotein, is a serum marker that has also been shown to positively correlate with the severity of endometriosis (Harada, 2002). Serum placental protein 14 (PP14; glycodelin-A) was initially shown to have adequate sensitivity (59 percent), but this has not been confirmed by other studies (Telimaa, 1989). Interleukin-6 (IL-6) serum levels above 2 pg/mL (90-percent sensitivity and 67-percent specificity) and tumor necrosis factor-α (TNF-α) peritoneal fluid levels above 15 pg/mL (100-percent sensitivity and 89-percent specificity) may be used to discriminate between those with or without endometriosis (Bedaiwy, 2002). Several other serum markers have been studied, with limited diagnostic accuracy (Bedaiwy, 2004). Most of these tests are rarely used outside of research settings.

Diagnostic Imaging

SONOGRAPHY

Both transabdominal and the more sensitive transvaginal (TVS) sonographic approaches have been used extensively in the diagnosis of endometriosis (see Chap. 2). Although TVS is the mainstay in evaluating symptoms associated with endometriosis and is accurate in detecting endometriomas, imaging of superficial endometriosis or endometriotic adhesions is inadequate. Small endometriotic plaques or nodules may occasionally be seen, but these findings are inconsistent (Carbognin, 2004).

More recently, sonovaginography, a technique involving vaginal saline instillation to more accurately localize rectovaginal endometriosis, and transrectal sonography have assisted in the diagnosis and evaluation of endometriosis (Brosens, 2003). Transvaginal sonography appears to be as effective as a transrectal approach in identifying posterior pelvic endometriosis, but the latter may delineate rectal involvement more accurately and may be more appropriate when planning surgery (Bazot, 2003).

Endometriomas can be diagnosed by TVS with adequate sensitivity in most settings if they are 20 mm in diameter or greater (Fig. 10-5). Specifically, sensitivity and specificity of TVS to diagnose endometriomas range from 64 to 90 percent and from 22 to 100 percent, respectively (Moore, 2002). Endometriomas often present as cystic structures with low-level internal echoes, and occasional thick septations, thickened walls, and echogenic wall foci (Athey, 1989; Patel, 1999). Color Doppler transvaginal sonography often demonstrates pericystic, but not intracystic, flow (Carbognin, 2004).

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging has been increasingly used as a noninvasive method for diagnosis of endometriosis. Small nodules may be recognized as hyperintense lesions on T1-weighted sequences, and plaque lesions have a similar appearance, with a variable signal on T2-weighted sequences (Carbognin, 2004). An endometrioma appears as a hyperintense mass on T1-weighted sequences, with a tendency towards hypointensity in T2-weighted sequences. A hypointense ring is often seen surrounding the endometrioma, which is enhanced after contrast administration (Fig. 10-6).

Diagnostic Laparoscopy

Diagnostic laparoscopy is the primary method used for diagnosing endometriosis (see Section 41-28, Laparoscopy) (Kennedy, 2005). Laparoscopic findings are variable and may include discrete endometriotic lesions, endometrioma, and adhesion formation.

ENDOMETRIOTIC LESIONS

The pelvic organs and pelvic peritoneum are typical locations for endometriosis. The appearance of these lesions by laparoscopy is varied and colors may include red (red, red-pink, or clear), white (white or yellow-brown), and black (black or black-blue) (Fig. 10-7). Dark lesions are pigmented by hemosiderin deposition from trapped menstrual debris. White and red lesions most commonly correlate with the histologic findings of endometriosis (Jansen, 1986). In addition to color differences, endometriotic lesions may differ morphologically. They can appear as smooth blebs on peritoneal surfaces, as holes or defects within the peritoneum, or as flat stellate lesions whose points are formed by surrounding scar tissue. Endometriotic lesions may be superficial or may deeply invade the peritoneum or pelvic organs. Although these findings may allow endometriosis to be diagnosed with accuracy, pain symptoms correlate poorly with findings at laparoscopy (Kennedy, 2005).

ENDOMETRIOMAS

Endometriomas are cystic endometrial lesions contained within the ovary. Typically, they have the appearance of smooth-walled, brown cysts filled with thick, chocolate-appearing liquid (Fig. 10-8). These ovarian masses may be unilocular, but are often multilocular when >3 cm in diameter (Nezhat, 1992b).

Laparoscopic visualization of ovarian endometriomas has a sensitivity and specificity of 97 percent and 95 percent, respectively (Vercellini, 1991). Because of this, ovarian biopsy is rarely required for diagnosis.

Pathologic Analysis

Although current guidelines do not require histologic evaluation for the diagnosis of endometriosis, some suggest that relying solely on laparoscopic findings in the absence of histologic confirmation often results in overdiagnosis (American Society for Reproductive Medicine, 1997). Specifically, the greatest discordance between laparoscopic and histologic findings is noted in scarred lesions (Marchino, 2005a; Walter, 2001). Histologic diagnosis requires the presence of both endometrial glands and stroma found outside the uterine cavity (Fig. 10-9). Additionally, hemosiderin deposition and fibromuscular metaplasia are frequently noted (Murphy, 2002). The gross appearance of endometriotic lesions often suggests certain microscopic findings. For example, when examined microscopically, red lesions are frequently vascularized, whereas white lesions more often display fibrosis and few vessels (Nisolle, 1997).

Diagnostic Algorithm

The approach to diagnosis and treatment of endometriosis depends on the presenting symptoms and goals of therapy (Fig. 10-10). If infertility is the presenting symptom, then fertility-preserving treatment without ovulation suppression will be required. In contrast, if the patient has severe, recalcitrant pain symptoms and has completed childbearing, definitive surgery may be warranted.

TREATMENT

Treatment for endometriosis depends on the woman's specific symptoms, severity of symptoms, location of endometriotic lesions, goals for treatment, and desire to conserve future fertility. The most important factor when determining the most appropriate management is whether a patient is seeking treatment for infertility or pain, as the treatment will differ based on the symptom (Olive, 2001).

Expectant Management

For many women, symptoms will preclude them from choosing expectant management. However, for those with mild symptoms or

for asymptomatic women diagnosed incidentally, expectant management may be appropriate. For example, Sutton and associates (1997) expectantly managed patients initially diagnosed by laparoscopy with minimal to moderate endometriosis. At second-look laparoscopy after 1 year, 29 percent of women had disease regression, 42 percent remained unchanged, and 29 percent had disease progression. Other investigations have shown similar rates of disease regression with expectant management (Thomas, 1987). However, studies evaluating infertile women have demonstrated lower fecundity rates after expectant management than following surgical treatment (Milingos, 2002; Marcoux, 1997). These studies are confined to patients with minimal to moderate endometriosis, and there are no well-designed trials examining the effect of expectant management on severe endometriosis.

Medical Treatment of Endometriosis-Related Pain

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

These agents nonselectively inhibit the cyclooxygenase isoenzymes 1 and 2 (COX-1 and COX-2), and within this group, the selective COX-2 inhibitors selectively inhibit the COX-2 isoenzyme. These enzymes are responsible for the synthesis of prostaglandins involved in the pain and inflammation associated with endometriosis. For example, endometriotic tissue has been shown to express COX-2 at greater levels than eutopic endometrium (Ota, 2001). Therefore, therapy aimed at lowering these prostaglandin levels may play a role in alleviating endometriosis-associated pain.

Nonsteroidal anti-inflammatory drugs are often first-line therapy in women with primary dysmenorrhea or pelvic pain prior to laparoscopic confirmation of endometriosis, and in women with minimal or mild pain symptoms associated with known endometriosis. Although animal models have demonstrated disease regression with NSAID treatment, few studies have critically evaluated their effectiveness in disease regression in surgically-confirmed endometriosis (Efstathiou, 2005). However, evidence exists for their efficacy in patients with dysmenorrhea and pelvic pain (Table 10-2) (Nasir, 2004). Due to the cardiovascular risks with long-term use of COX-2 inhibitors, these medications should be used at the lowest possible dose and for the shortest duration necessary (Jones, 2005).

Table 10-2 Commonly Used Oral Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) in the Treatment of Endometriosis-Associated Dysmenorrhea

Generic Name	Trade Name	Dosage	Adverse Effects
Ibuprofen	Motrin, Advil, Nuprin	400 mg every 4â€“6 h	Nausea; epigastric pain; anorexia; constipation; gastrointestinal bleeding
Naproxen	Naprosyn, Aleve	500 mg initially, then 250 mg every 6â€“8 h	Same as above
Naproxen sodium	Anaprox	550 mg initially, then 275 mg every 6â€“8 h	Same as above
Mefenamic acid	Ponstel	500 mg initially, then 250 mg every 6 h, starting with menses and continued for 3 days	Same as above
Ketoprofen	Orudis, Oruvail	50 mg q6â€“8 h	Same as above

COMBINATION ORAL CONTRACEPTIVES

These agents have been a mainstay for the treatment of pain associated with endometriosis. Although no randomized controlled trials have compared COCs with placebo, abundant observational evidence supports the role of COCs in the relief of endometriosis-related pain (Vercellini, 1993; Vessey, 1993). These drugs appear to act by inhibiting gonadotropin release, decreasing menstrual flow, and decidualizing implants. In addition, COCs have the added benefit of contraception, suppression of ovulation, and other noncontraceptive benefits (see Table 5-6).

These drugs can be used conventionally in a cyclic regimen or may be used continuously, without a break for withdrawal menses. The continuous regimen may be preferable for its decreased frequency of menses for women who fail to achieve pain relief with cyclic COC therapy (Vercellini, 2003b; Wiegratz, 2004). Traditionally, monophasic COCs have been used in the treatment of endometriosis, but no evidence supports their clinical superiority to multiphasic COCs. Additionally, low-dose COCs (containing 20 μg ethinyl estradiol) have not proved superior to conventional-dose COCs for the treatment of endometriosis and may lead to higher rates of abnormal bleeding (Gallo, 2005).

PROGESTINS

Progestational agents have long been used in the treatment of endometriosis. Progestins are known to antagonize estrogenic effects on the endometrium, causing initial decidualization and subsequent endometrial atrophy. Progestins have been administered for the treatment of endometriosis in numerous ways and include oral progestins, depot medroxyprogesterone acetate (DMPA), a levonorgestrel-releasing intrauterine device (IUD), and the newer selective progesterone-receptor modulators (SPRMs).

Although progestin-based therapy is commonly used to effectively treat symptoms, there has been only one well-designed, randomized controlled trial comparing the effect of placebo with medroxyprogesterone acetate (MPA), 100 mg orally daily, given for 6 months. At second-look laparoscopy, partial or total resolution of peritoneal implants in 60 percent of women was noted, compared with 18 percent in the placebo group. Furthermore, pelvic pain and defecatory pain were significantly reduced (Telimaa, 1987). Side effects of high-dose MPA included acne, edema, weight gain, and irregular menstrual bleeding. In practice, MPA is prescribed in dosages ranging from 20 to 100 mg daily. Alternatively, MPA may be given intramuscularly in depot form in a dosage of 150 mg every 3 months. In depot form, MPA may delay resumption of normal menses and ovulation and should not be used in women contemplating imminent pregnancy.

Norethindrone acetate (NETA) is a 19-nortestosterone synthetic progestin that has been used in the treatment of endometriosis. In one study, investigators administered an initial oral dosage of NETA, 5 mg daily, with increases of 2.5 mg daily until amenorrhea or a maximal dosage of 20 mg daily was reached. They found an approximately 90-percent reduction in dysmenorrhea and pelvic pain (Muneyyirci-Delale, 1998). Additionally, NETA has been shown to be effective in conjunction with long-term gonadotropin-releasing hormone (GnRH) agonist therapy for endometriosis. In this fashion, NETA, 5 mg administered orally daily, in conjunction with prolonged GnRH agonist therapy, results in significant resolution of symptoms while protecting against bone loss (Hornstein, 1998; Surrey, 2002).

The levonorgestrel-releasing intrauterine system (LNG-IUS) (Mirena, Berlex, Montville, NJ) has traditionally been used for contraception and dysfunctional uterine bleeding (see Fig. 5-5). Recently, the LNG-IUS, however, has been used for the treatment of endometriosis. This IUD delivers levonorgestrel directly to the endometrium and is effective for up to 5 years. An observational trial revealed symptomatic improvement in patients with endometriosis using the LNG-IUS, with symptom improvement continuing up to 30 months (Lockhat, 2005). The continuation rate at 3 years, however, was only 56 percent, mostly due to intolerable bleeding, persistent pain, and weight gain. A randomized controlled trial comparing LNG-IUS with GnRH agonist therapy showed equivalent improvement in pain symptoms, without the concomitant hypoestrogenism that accompanies GnRH agonist treatment (Petta, 2005). Accordingly, these recent findings make the LNG-IUS an attractive option in treating women with endometriosis.

SELECTIVE PROGESTERONE RECEPTOR MODULATORS

A new and novel option in the treatment of endometriosis has been the use of selective progesterone-receptor modulators (SPRMs). These are progesterone-receptor ligands (molecules that bind and activate or inactivate the progesterone receptor) and have both progesterone antagonist and antagonist activities (Elger, 2000). One common SPRM, mifepristone (RU486), is a controversial abortifacient that predominantly possesses antiprogestational activity. It has also been studied in women with endometriosis and was found to reduce pelvic pain and extent of endometriosis, when used for 6 months at oral dosages of 50 mg daily (Kettel, 1996). Asoprisnil (J867) is a SPRM that induces endometrial atrophy and amenorrhea. Currently in Phase III trials for the treatment of leiomyomas and endometriosis, asoprisnil in Phase II studies improved dysmenorrhea and pelvic pain symptoms, whereas amenorrhea was dose dependent (Chwalisz, 2005). These novel agents hold promise for future treatment of endometriosis.

ANDROGENS

The first medication approved for the treatment of endometriosis in the United States was the androgen danazol. This agent is a synthetic androgen that is an isoxazole derivative of 17-α-ethinyl testosterone. The predominant mechanism of action appears to be suppression of midcycle luteinizing hormone (LH) surge, creating a chronic anovulatory state (Floyd, 1980). Danazol occupies receptor sites on sex-hormone binding globulin (SHBG) to increase serum free testosterone levels and also binds directly to androgen and progesterone receptors. As a result, danazol creates a hypoestrogenic, hyperandrogenic state, inducing endometrial atrophy in endometriotic implants (Fedele, 1990).

Danazol at dosages of 200 mg given orally three times daily proved superior to placebo for the reduction of endometriotic implants and pelvic pain symptoms after 6 months of therapy (Telimaa, 1987). The recommended dosage of danazol is 600 to 800 mg daily. Unfortunately, significant androgenic side effects develop at this dosage and include acne, hot flashes, hirsutism, adverse serum lipid profiles, voice deepening (possibly irreversible), elevation of liver enzymes, and mood changes. Moreover, due to possible teratogenicity, this medication should be taken in conjunction with effective contraception. Because of this adverse side-effect profile, danazol is prescribed less frequently, and when administered, its duration should be limited.

Gestrinone (ethylnorgestrienone; R2323) is an antiprogestational agent prescribed in Europe for the treatment of endometriosis. Although it has antiprogestational, antiestrogenic, and androgenic effects, it predominantly induces a progesterone withdrawal effect and decreases the number of estrogen and progesterone receptors. Endocrinologic changes during therapy with gestrinone show that basal concentrations of gonadotropin levels remain unchanged, estradiol concentrations vary, and free testosterone levels increase, with concomitant androgenic side effects (Forbes, 1993).

Gestrinone equals the effectiveness of danazol and of GnRH agonists for relief of endometriosis-related pain (Prentice, 2000a). Furthermore, during 6 months of treatment, gestrinone was not associated with the bone density loss commonly seen with GnRH agonist use and was more effective in persistently decreasing moderate to severe pelvic pain (Gestrinone Italian Study Group, 1996). Unfortunately, gestrinone appears to lower high-density lipoprotein (HDL) levels. Gestrinone is administered orally, 2.5 to 10 mg weekly, given daily or three times weekly.

GNRH AGONISTS

Endogenous pulsatile release of GnRH leads to pulsatile secretory activity of the gonadotropes within the anterior pituitary. This pulsatile release results in pituitary release of gonadotropins, with subsequent ovarian steroidogenesis and ovulation. Continuous, nonpulsatile GnRH administration, however, results in pituitary desensitization and subsequent loss of ovarian steroidogenesis (Rabin, 1980). These features allow pharmacologic use of GnRH agonists for the treatment of endometriosis. With loss of ovarian estradiol production, the hypoestrogenic environment removes the stimulation normally provided to the endometriotic implants and creates a pseudomenopausal state during treatment.

Pain Improvement

Agonists may be used prior to laparoscopy in women with chronic pelvic pain and clinical suspicion of endometriosis. A list of clinically used GnRH agonists is found in Table 9-3. After 3 months of GnRH agonist treatment (depot leuprolide acetate; Lupron Depot, TAP Pharmaceutical Products, Lake Forest, IL), pain scores were significantly reduced compared with placebo (Ling, 1999). Subsequent laparoscopy revealed that 93 percent of these women had surgically-diagnosed endometriosis. Accordingly, many suggest that in similar patients, depot leuprolide acetate may be used empirically in lieu of laparoscopy, for satisfactory improvement in symptoms.

Numerous studies have demonstrated the effectiveness of GnRH agonist therapy to improve pain symptoms in women with surgically-confirmed endometriosis. For example, in their randomized controlled trial, Dlugi and co-workers (1990) compared depot leuprolide acetate with placebo and found significant decreases in the severity of pelvic pain. Similar findings were obtained comparing buserelin, another GnRH agonist, with expectant management during a 6-month period (Fedele, 1993). The GnRH agonists seem to provide greater relief when administered for 6 months compared with 3 months (Hornstein, 1995b).

In trials with other drugs for the treatment of endometriosis, GnRH agonists compared favorably. Vercellini and associates (1993), in their randomized controlled trial found equal degrees of pain improvement when comparing GnRH agonist therapy with a low-dose cyclic COC regimen. Dyspareunia, however, was less in the GnRH agonistâ€“treated group. In addition, a meta-analysis

revealed that GnRH agonists were equally effective in improving pain scores and decreasing endometriotic implants compared with danazol (Prentice, 2000b).

Add-Back Therapy

Concerns about the long-term effects of prolonged hypoestrogenism preclude extended treatment with GnRH agonists. Hypoestrogenic symptoms include hot flushes, insomnia, reduced libido, vaginal dryness, and headaches. Of particular concern is the effect of the hypoestrogenic state on bone mineral density (BMD). Evidence indicates that there are decreases in spine and hip BMD at 3 and 6 months of GnRH agonist therapy, with only partial recovery at 12 to 15 months after treatment (Orwoll, 1994). Because of the increased risk of osteoporosis, therapy is usually limited to the shortest possible duration (usually no greater than 6 months). Additionally, estrogen in the form of COCs may be added to GnRH agonist therapy to counteract the bone loss and is termed *add-back therapy* (Fig. 10-11) (Carr, 1995). Occasionally a GnRH agonist may be used for longer periods, with hormonal add-back therapy in the form of norethindrone acetate, 5 mg orally given daily, with or without conjugated equine estrogen (Premarin, Wyeth, Madison, NJ) 0.625 mg daily for 12 months. This regimen has been shown to provide extended pain relief beyond the duration of treatment and preservation of bone density (Surrey, 2002).

AROMATASE INHIBITORS

As previously mentioned, endometrial tissue locally produces aromatase, the enzyme responsible for estrogen synthesis. In endometriotic tissue, estrogen may be produced locally through aromatization of circulating androgens. This may be the reason for postmenopausal endometriosis and for intractable symptoms in some women despite treatment. An aromatase inhibitor was first used for endometriosis treatment in a woman with postmenopausal endometriosis after total hysterectomy and bilateral salpingo-oophorectomy (Takayama, 1998). The patient experienced significant pain relief, significant endometriotic lesion size reduction, and a 6-percent reduction in lumbar spine BMD after 9 months of treatment. Subsequently, further study has examined aromatase inhibitors in conjunction with low-dose, continuous COC add-back therapy for 6 months. This small Phase II trial revealed a significant pain reduction in 14 of 15 women with previously intractable pain from endometriosis (Amsterdam, 2005). Aromatase inhibitors have similar hypoestrogenic side-effect profiles as GnRH agonists, but hold promise in severe, refractory cases of endometriosis.

Surgical Treatment of Endometriosis-Related Pain

LESION REMOVAL AND ADHESIOLYSIS

Because the primary method for diagnosis of endometriosis is laparoscopy, surgical treatment of endometriosis at the time of diagnosis is an attractive option. There are numerous studies examining removal of endometriotic lesions, either through excision or ablation. Unfortunately, many of these studies are uncontrolled or retrospective. However, a single randomized controlled trial comparing laparoscopic ablation of endometriotic lesions and laparoscopic uterine nerve ablation with diagnostic laparoscopy performed alone revealed significant symptom relief in 63 percent of women in the ablation group, compared with 23 percent in the expectant management group. Unfortunately, recurrence is common following surgical excision. Jones (2001) demonstrated pain recurrence in 74 percent of patients at a mean time following surgery of 73 months. The median time for recurrence was 20 months.

The optimal method of endometriotic implant ablation for maximal symptom relief is controversial. Laser ablation does not appear to be more effective than conventional electrosurgical ablation of endometriosis (Blackwell, 1991). A randomized controlled trial comparing ablation with excision of endometriotic lesions in women with stage I or II endometriosis revealed similar reductions in pain scores at 6 months (Wright, 2005). For deeply infiltrative endometriosis, some authors have advocated radical surgical excision, although well-designed trials are lacking (Chapron, 2004).

Adhesiolysis is postulated to effectively treat pain symptoms in women with endometriosis by restoring normal anatomy. Unfortunately, most studies are poorly designed and retrospective. As a result, a definitive link between adhesions and pelvic pain is unclear (Hammoud, 2004). For example, one randomized controlled trial demonstrated no overall pain relief from adhesiolysis compared with expectant management (Peters, 1992). However, within this study, one woman with severe, dense vascularized bowel adhesions experienced pain relief following adhesiolysis.

ENDOMETRIOMA RESECTION

Endometriomas are often treated surgically, as ovarian masses often prompt surgical investigation, and their associated symptoms may lead to more aggressive therapy (see Chap. 9, Surgical Excision). Historically, endometriomas have been treated by total ovarian cystectomy or by aspiration coupled with ablation of the cyst capsule (see Section 41-33, Laparoscopic Ovarian Cystectomy). One randomized controlled trial has compared cystectomy with surgical drainage and bipolar coagulation of the endometrioma's inner lining (Beretta, 1998). Cystectomy lead to lower rates of pelvic pain compared with drainage and coagulation (10 percent versus 53 percent). Additionally, cumulative pregnancy rates were higher following cystectomy during 24-month surveillance (67 percent versus 24 percent). Endometriomas may recur. Liu and co-workers (2007) found an approximately 15-percent rate of recurrence at 2 years following initial surgery.

PRESACRAL NEURECTOMY

For some women, transection of presacral nerves lying within the interiliac triangle may provide relief of chronic pelvic pain. Results from a recent randomized controlled trial revealed significantly greater pain relief at 12 months postoperatively in women treated with presacral neurectomy (PSN) and endometriotic excision compared with endometriotic excision alone (86 percent versus 57 percent) (Zullo, 2003). However, all of these women had midline pain, and an earlier meta-analysis demonstrated a significant decrease in pelvic pain after PSN compared with that following more conservative procedures, but only in those with midline pain (Wilson, 2000). Neurectomy may be performed laparoscopically, but it is technically challenging. For these reasons, PSN is used in a limited manner and not recommended routinely for management of endometriosis-related pain.

ABDOMINAL VERSUS LAPAROSCOPIC APPROACH

All of the surgical procedures listed above can be approached either through laparotomy or laparoscopy. Operative laparoscopy has been used for treatment of ovarian endometriomas for over 20 years, and strong evidence supports laparoscopy over laparotomy in managing benign ovarian masses (see Chap 9, Laparoscopy) (Mais, 1995; Reich, 1986; Yuen, 1997). Unfortunately, a large number of endometriomas are still treated by laparotomy, with 50 percent of physicians surveyed in the United Kingdom still treating endometriomas in this manner (Jones, 2002). Although laparoscopic treatment of endometrioma carries an associated 5 percent risk for conversion to laparotomy, because of its efficacy and low rates of postoperative morbidity, laparoscopy should be

the primary procedure of choice (Canis, 2003).

Studies also demonstrate the effectiveness and low morbidity rates in laparoscopic excision of endometriotic implants, and laparoscopic presacral neurectomy appears to be as effective as laparotomy (Nezhat, 1992a; Redwine, 1991). Moreover, adhesiolysis should be performed by laparoscopy when safe, and laparoscopy leads to less de novo adhesion formation than laparotomy (Gutt, 2004).

HYSTERECTOMY WITH BILATERAL OOPHORECTOMY

Hysterectomy with bilateral oophorectomy is the definitive and most effective therapy for women with endometriosis who do not wish to retain their reproductive function. Women who forego bilateral oophorectomy during hysterectomy for endometriosis have a sixfold greater risk of recurrent chronic pelvic pain (CPP) and an eightfold greater risk of requiring additional surgery compared with women who undergo concomitant bilateral oophorectomy (Namnoum, 1995). For this reason, hysterectomy alone has no role in the treatment of CPP secondary to endometriosis.

Despite its effectiveness in the treatment of endometriosis, limitations of hysterectomy with bilateral oophorectomy include surgical risks, pain recurrence, and the effects of hypoestrogenism. Of women who undergo hysterectomy and bilateral oophorectomy for CPP, 10 percent have recurrent symptoms and 3.7 percent required additional pelvic surgery. Accordingly, a consensus conference recommendation from an expert panel of gynecologists in the United States stated that hysterectomy with bilateral oophorectomy should be reserved for women with symptomatic endometriosis who have completed childbearing and recognize the risk of premature hypoestrogenism, including possible osteoporosis and decreased libido (Gambone, 2002).

APPROACH TO HYSTERECTOMY WITH OOPHORECTOMY

There is no single correct procedure for hysterectomy and bilateral oophorectomy for patients with endometriosis, and surgery may be completed laparoscopically, abdominally, or vaginally (see Section 41-19, Hysterectomy). However, adhesions and distorted anatomy secondary to endometriosis often makes a laparoscopic or vaginal approach more difficult. In addition, the need to remove ovaries may make a vaginal approach less feasible. Accordingly, the choice of procedure will depend on equipment availability, operator experience, and extent of disease.

POSTOPERATIVE HORMONE REPLACEMENT

In response to concerns of increased risk of cardiovascular disease and breast cancer with the use of postmenopausal hormone therapy (HT), attention has been directed toward indiscriminant HT use (Anderson, 2004; Rossouw, 2002). Women with endometriosis who undergo hysterectomy with oophorectomy, however, represent a subset of menopausal women who may be better candidates for HT than women who go through natural menopause. First, women who undergo surgical menopause are usually younger and would likely benefit from replacement of estrogen that is lost by removal of functional ovaries. Estrogen replacement should be considered in women with a surgical menopause for prevention of hypoestrogenic side effects such as hot flashes, osteoporosis, or decreased libido. It has been suggested to treat these women until the time of expected natural menopause, although evidence is lacking.

Although unopposed estrogen may be used in postmenopausal women in the absence of a uterus, disease recurrence has been reported with this therapy in women with severe endometriosis first treated with hysterectomy and oophorectomy (Taylor, 1999). Symptoms required repeat surgery, and did not recur with combined estrogen and a progestin. Additionally, cases of endometrial carcinoma have been reported in women with endometriosis treated with unopposed estrogen after hysterectomy and oophorectomy (Reimnitz, 1988; Soliman, 2004). This is a rare phenomenon and may arise from incompletely resected pelvic endometriosis. Therefore, adding a progestin to the estrogen replacement therapy may be considered in women with severe endometriosis treated surgically.

TREATMENT OF ENDOMETRIOSIS-RELATED INFERTILITY

Medical therapy used for treatment of endometriosis-related pain has not been shown to be effective in increasing fecundity in women with endometriosis (Hughes, 2003). Surgical ablation has been suggested to be beneficial for women with infertility and minimal to mild endometriosis, although the effect was minimal (Marcoux, 1997). Moderate to severe endometriosis may be treated with surgery to restore normal anatomy and tubal function. However, there are no well-designed trials examining the role of

surgery for subfertility in women with severe endometriosis. Alternatively, patients with endometriosis and infertility are candidates for fertility treatments such as controlled ovarian hyperstimulation, intrauterine insemination, and in vitro fertilization (see Chap. 20).

PELVIC PAIN: INTRODUCTION

Acute and chronic lower abdominal pain are common complaints in office and emergency room settings. However, they vary dramatically by definition, predominant etiologies, and neurophysiology. The mechanisms underlying the perception of pain are not yet fully defined but appear to involve interactions between neurologic, psychological, immunologic, and endocrine factors.

PAIN PATHOPHYSIOLOGY

When categorized, pain may be considered *visceral* or *somatic* depending on the type of afferent nerve fibers involved. Additionally, pain may be described by the neurophysiologic steps that produce it and can be defined as *inflammatory* or *neuropathic* (Kehlet, 2006). Both categorizations are helpful in diagnosing the underlying sources of pain and selecting effective treatment.

Somatic Pain

Somatic pain stems from nerve afferents of the somatic nervous system, which innervates the parietal peritoneum, skin, muscles, and subcutaneous tissues. This pain is typically sharp, localized, and found on either the right or left within dermatomes that correspond to the innervation of involved tissues (Fig. 11-1).

Dermatome maps. A dermatome is an area of skin supplied by a single spinal nerve. **A.** Body dermatomes. *(From McKinley, 2006, with permission.)* **B.** Perineal dermatomes.

Visceral Pain

Visceral pain stems from afferent fibers of the autonomic nervous system, which transmit information from the viscera and visceral peritoneum. Noxious stimuli typically involve stretching, distension, ischemia, or spasm of abdominal organs. The visceral afferent fibers that transfer these stimuli are sparse, and the resulting diffuse sensory input leads to pain that is often described as a generalized, dull ache.

Visceral pain often localizes to the midline because visceral innervation of abdominal organs is typically bilateral (Flasar, 2006). Visceral afferents follow a segmental distribution, and visceral pain is typically localized by the brain's sensory cortex to an approximate spinal cord level. That level is determined by the embryologic origin of the organ involved. For example, midgut organs, such as the small bowel, appendix, and cecum, cause periumbilical pain. Hindgut organs, such as the colon and intraperitoneal portions of the genitourinary tract, cause pain in the suprapubic or hypogastric area (Gallagher, 2004).

Visceral afferent fibers are poorly myelinated and action potentials may easily spread from them to impact adjacent somatic nerves. As a result, visceral pain may at times be referred to dermatomes that correspond to the impacted somatic nerve fibers (Giamberardino, 2003). In addition, both peripheral somatic and visceral nerves often synapse in the spinal cord at the same dorsal horn neurons. These neurons, in turn, relay sensory information to the brain. The cortex recognizes the signal as coming from the same dermatome regardless of its visceral or somatic nerve origin. This phenomenon, termed *viscerosomatic convergence* , leads to difficulty in a patient distinguishing internal organ pain from abdominal wall or pelvic floor pain (Fig. 11-2) (Perry, 2003).

FIGURE 11-2

Viscerosomatic convergence. Nociceptive impulses originating from a viscera may impact dorsal horn neurons that synapse concurrently with peripheral somatic nerves. These impulses may then be perceived by the brain as coming from a peripheral somatic source rather than the viscera.

Inflammatory Pain

With acute pain, noxious stimuli such as a knife cut, burn, or crush injury activate sensory pain receptors, more formally termed *nociceptors* . Action potentials travel from the periphery to dorsal horn neurons in the spinal cord. Here, reflex arcs may lead to muscle contraction, which immediately removes and protects the body from harm. Additionally within the spinal cord, sensory information is augmented or dampened and may then be transmitted to the brain. In the cortex, it is recognized as pain (Janicki, 2003). After an acute stimulus is eliminated, activity of the nociceptor quickly diminishes.

If tissues are injured, then inflammation typically follows. Commonly during an inflammatory process, sensitizing mediators are released into affected tissues and lower the conduction threshold of nociceptors in these tissues. This is termed *peripheral sensitization* . Similarly, neurons within the spinal cord display increased excitability, termed *central sensitization.* As a result, within inflamed tissues, the perception of pain is increased relative to the strength of the external stimulus (Kehlet, 2006).

As inflammation subsides and healing ensues, the increased sensitivity to stimuli and thus the perception of pain resolves.

Neuropathic Pain

In some individuals, sustained noxious stimuli can lead to persistent central sensitization and to a loss of neuronal inhibition that is permanent. As a result, a decreased threshold to painful stimuli remains despite resolution of the inciting stimuli (Butrick, 2003). This persistence characterizes neuropathic pain, which is felt to underlie many chronic pain syndromes (Fig. 11-3). The concept of neuropathic pain helps explain in part why many with chronic pain have pain disproportionately greater to the amount of co-existent disease found.

FIGURE 11-3

Diagram describing theoretical steps required for genesis of chronic pain syndromes. IBS = irritable bowel syndrome; IC = interstitial cystitis. *(Redrawn from Buttrick, 2003, with permission.)*

During central sensitization, neurons within spinal levels above or below those initially affected may eventually become involved. This phenomenon results in chronic pain that may be referred across several spinal cord dermatomes.

Thus, in assessing patients with chronic pain, a clinician may find an ongoing inflammatory condition, in which inflammatory pain dominates. However, for many, pain may be neuropathic. For these, evaluation may ultimately reveal no or minimal current pathology and treatment thus focuses on management of pain symptoms.

ACUTE PAIN

Acute lower abdominal and pelvic pain are common complaints. The definition of these varies based on duration, but in general, discomfort is present less than 7 days. The sources of acute lower abdominal and pelvic pain are extensive and a thorough history and physical examination can aid in narrowing the list (Table 11-1).

HISTORY

In addition to a thorough medical and surgical history, a verbal description of the pain and its associated factors is essential. For example, duration can be informative, and pain with abrupt onset may be more often associated with organ torsion, rupture, or

ischemia.

Moreover, the nature of pain may add value. Patients with visceral pathology may describe midline pain that is diffuse, dull, achy, or cramping. They may repeatedly shift or roll to one side to find a comfortable position.

If the underlying pathology stems from infection or necrosis, then inflammation of the adjacent parietal peritoneum may create a sharp pain that is localized to a corresponding dermatome. Alternatively, such sharp, localized pain may also involve pathology of specific muscles or isolated areas of skin or subcutaneous tissues. In either instance, with somatic pain, patients classically rest motionless to avoid movement of the affected peritoneum, muscle, or skin.

Colicky pain may reflect bowel obstructed by adhesion, neoplasia, stool, or hernia, or may result from increased bowel peristalsis in those with irritable or inflammatory bowel disease or infectious gastroenteritis. Alternatively, forceful uterine contractions with the passage of products of conception, pedunculated submucous leiomyomas, or endometrial polyps may create colic. In addition, stones in the lower urinary tract may cause spasms of pain as they are passed.

Associated symptoms may also direct diagnosis. For example, absence of dysuria, hematuria, frequency, or urgency will exclude urinary pathology in most instances. Gynecologic causes are often associated with vaginal bleeding, vaginal discharge, dyspareunia, or amenorrhea. Alternatively, exclusion of diarrhea, constipation, or gastrointestinal bleeding lowers the probability of gastrointestinal (GI) disease.

Vomiting complaints, however, are less informative. However, the temporal relationship of vomiting to the pain may be helpful. In the surgical abdomen, if vomiting is present it usually follows as a response to pain and is a result of vagal stimulation. This vomiting is typically severe and occurs without nausea. Conversely, if vomiting is noted prior to pain or concurrent with it, a surgical abdomen is less likely (Miller, 2006).

In general, well-localized pain or tenderness persisting for longer than 6 hours and unrelieved by analgesics, has an increased likelihood of acute peritoneal pathology.

PHYSICAL EXAMINATION

Vital Signs

Initial examination begins with assessment of a woman's general appearance, including facial expression, diaphoresis, pallor, and degree of agitation. Vital signs are assessed, and elevated temperature, tachycardia, and hypotension should prompt an expedited evaluation, as the risk for intra-abdominal pathology increases with their presence. Constant low-grade fever is common in inflammatory conditions such as diverticulitis and appendicitis, and higher temperatures may be seen with pelvic inflammatory disease (PID), advanced peritonitis, or pyelonephritis.

Pulse and blood pressure evaluation should assess orthostatic changes if intravascular hypovolemia is suspected. A pulse increase of 30 beats per minute or a systolic blood pressure drop of 20 mm Hg or both, between lying and standing after 1 minute, is often reflective of hypovolemia. If noted, establishment of intravenous access and rehydration may be required prior to completion of the examination. However, certain neurologic disorders and medications, such as tricyclic antidepressants or antihypertensives may also produce similar orthostatic blood pressure changes (Saperston, 2004).

Abdominal Examination

Visual inspection of the abdomen focuses on prior surgical scars, which may increase the possibility of bowel obstruction from postoperative adhesions or incisional hernia. Additionally, abdominal distension may be seen with bowel obstruction, perforation, or ascites. After inspection, auscultation of the abdomen may identify hyperactive or high-pitched bowel sounds characteristic of bowel obstruction. Hypoactive sounds, however, provide less diagnostic information.

Palpation of the abdomen should systematically explore each abdominal quadrant and begin away from the area of indicated pain. Peritoneal irritation is suggested by rebound tenderness or by abdominal rigidity due to involuntary guarding or reflex spasm of the abdominal muscles.

Pelvic Examination

In general, pelvic examination should be performed in reproductive-aged women, as gynecologic pathology and complications of pregnancy are a common cause of pain in this age group. The decision to proceed with this examination in geriatric and pediatric patients may be based on clinical information.

Of findings, purulent vaginal discharge or cervicitis may reflect PID (see Chap. 3, Pelvic Inflammatory Disease). Vaginal bleeding may stem from pregnancy complications, benign or malignant reproductive tract neoplasia, or acute vaginal trauma (see Chap. 8). Pregnancy, leiomyomas, and adenomyosis are common causes of uterine enlargement, and the former two may also create uterine softening (see Chap. 9, Uterus). Cervical motion tenderness is commonly associated with peritoneal irritation and may be seen with PID, appendicitis, diverticulitis, and intra-abdominal bleeding. A tender adnexal mass may reflect ectopic pregnancy, tubo-ovarian abscess, or ovarian cyst with torsion, hemorrhage, or rupture. Alternatively, a tender mass may reflect an abscess involving the appendix or colon diverticulum. Rectal examination can add additional information regarding the source and size of pelvic masses as well as the possibility of colorectal pathologies. Stool guaiac testing for occult blood, although less sensitive when not performed serially, is still warranted in many cases (Rockey, 2005).

In emergency room settings, women with acute pain may experience waits between an initial assessment and laboratory testing, specialist consultation, or radiologic imaging. For these patients, recent literature supports early administration of analgesia. Fears that analgesia will mask patient symptoms and hinder accurate diagnosis have not been supported (McHale, 2001; Pace, 1996). Thus, barring significant hypotension or drug allergy, morphine sulfate may be administered and increased as needed in these situations.

LABORATORY TESTING

Despite benefits from a thorough history and physical examination, the sensitivity of these two in diagnosing abdominal pain is low (Gerhardt, 2005). Thus, laboratory and diagnostic testing are typically required. In women with acute abdominal pain, complications of pregnancy are common. Thus, either urine or serum β-hCG testing is recommended in those of reproductive age without a history of hysterectomy. Complete blood count (CBC) can aid in assessment of hemorrhage, both vaginal and intra-abdominal, and assess the possibility of infection. Urinalysis may be used to evaluate possible urolithiasis or cystitis. In addition, microscopic evaluation and culture of vaginal discharge can add support to clinically suspected cases of PID.

RADIOLOGIC IMAGING

In women with acute pelvic pain, sonography is commonly used (Lambert, 2004; Okaro, 2004). In most cases, a transvaginal approach offers superior resolution of reproductive organs. However, if pelvic organs are significantly large and lie outside the true pelvis, transabdominal sonography may be necessary to image entire structures. Moreover, in cases in which sonographic findings are equivocal or nondiagnostic, computed tomography (CT) is widely used for its ability to detect a great variety of bowel, reproductive tract, and urinary disorders (Leschka, 2005). Computed tomography has superior sensitivity compared with abdominal radiography. Thus, many advocate it as a primary tool in settings in which radiography would be ordered, such as with suspected bowel obstruction, perforation, or generalized nontraumatic abdominal pain (Ahn, 2002; MacKersie, 2005).

LAPAROSCOPY

Operative laparoscopy is the primary treatment for appendectomy, ovarian torsion, and for ruptured tubal ectopic pregnancy or ruptured ovarian cyst associated with symptomatic hemorrhage. Moreover, diagnostic laparoscopy may be useful if no pathology can be identified by conventional diagnostics. However, in stable patients with acute abdominal pain, noninvasive testing is typically fully exhausted before considering this approach (Sauerland, 2006).

CHRONIC PAIN

Persistent pain symptoms in women may take several forms and include dysmenorrhea, dyspareunia, chronic pelvic pain (CPP), musculoskeletal pain, intestinal cramping, or dysuria. The list of pathologies that may underlie these chronic pain symptoms is extensive and includes both psychological and organic disorders (Table 11-2). Moreover, pathology in one organ can commonly lead to dysfunction in adjacent systems. As a result, a woman with chronic pain may have more than one cause of pain and overlapping symptoms. Thus, a comprehensive evaluation of multiple organ systems and psychological state is essential for complete treatment.

Chronic Pelvic Pain

Chronic pelvic pain is a common gynecologic problem and Mathias (1996) estimated its prevalence in reproductive-aged women at 15 percent. There is no universally accepted definition of chronic pelvic pain. However, many investigators distinguish it from dysmenorrhea and dyspareunia and define it as noncyclic pain that persists for 6 or more months; localizes to the pelvis, infraumbilical anterior abdominal wall, or lumbosacral back or buttocks; and leads to degrees of functional disability (American College of Obstetricians and Gynecologists, 2004).

ETIOLOGY

Causes of chronic pelvic pain fall within a broad spectrum, but endometriosis, symptomatic leiomyomas, interstitial cystitis, and irritable bowel syndrome are commonly diagnosed. Diagnosis and treatment of pain related to endometriosis is discussed fully in Chapter 10, Patient Symptoms. Evaluation and management of chronic pain secondary to leiomyomas is found in Chapter 9, Pelvic Discomfort and Dysmenorrhea.

The pathophysiology of CPP is unclear in many cases and may have a significant association with neuropathic pain described earlier (Neuropathic Pain). Chronic pelvic pain shows increased association with irritable bowel syndrome, interstitial cystitis, and vulvodynia. These are also considered by many to be chronic visceral pain syndromes stemming from neuropathic pain (Janicki, 2003).

HISTORY

More than with many other gynecologic complaints, a detailed history and physical examination is integral to diagnosis. A pelvic pain questionnaire can be used initially to obtain information. One example is available from the International Pelvic Pain Society and may be downloaded free of charge at http://www.pelvicpain.org/pdf/FRM_Pain_Questionnaire.pdf . At minimum, the series of questions found in Table 11-3 may provide valuable information.

Table 11-3 Brief Historical Survey in the Evaluation of Chronic Pelvic Pain

1. How old are you?
2. How many pregnancies have you had?
3. Where does it hurt?
4. How much does it hurt?
5. What is the quality or character of your pain?
6. Do you have pain with your periods?
7. Does your pain worsen with menses or just before menses?
8. Is there any cyclic pattern to your pain? Is it the same 24 hours a day, 7 days a week?
9. Is your pain constant or intermittent?
10. When and how did your pain start and how has it changed?
11. Did pain start initially as menstrual cramps (dysmenorrhea)?
12. What makes your pain better?
13. What makes your pain worse?
14. Do you have pain with deep penetration during intercourse? If so, does it continue afterwards?
15. Have you ever been diagnosed with or treated for a sexually transmitted disease or pelvic inflammatory disease?
16. What form of birth control do you use and have you used in the past?
17. Have you ever had any kind of surgery?
18. What prior evaluations or treatments have you had for your pain? Have any of the previous treatments helped?
19. How has the pain affected your quality of life?
20. Are you depressed or anxious?
21. Are you taking any drugs?
22. Have you been or are you now being abused physically or sexually? Are you safe?
23. What other symptoms or health problems do you have?
24. What do you believe or fear is the cause of your pain?

Obstetric History

Pregnancy and delivery can be traumatic to neuromuscular structures and have been linked with pelvic organ prolapse, pelvic floor muscle myofascial pain syndromes, and symphyseal or sacroiliac joint pain. In addition, injury to the ilioinguinal or iliohypogastric nerves during Pfannenstiel incision for cesarean delivery may lead to lower abdominal wall pain even years after the initial injury (Whiteside, 2003). Alternatively, in a nulliparous woman with infertility, pain may stem from endometriosis, pelvic adhesions, or pelvic inflammatory disease.

Surgical History

Prior abdominal surgery increases a woman's risk for pelvic adhesions, especially if infection, bleeding, or large areas of denuded peritoneal surfaces were involved. In addition, certain disorders persist or commonly recur, and thus information regarding prior surgeries for endometriosis, adhesive disease, or malignancy should be sought.

Pain Characteristics

Various pain scales improve the assessment of pain, and the Visual Analog Scale (VAS), Verbal Descriptor Scales (VDS), and McGill Pain Questionnaire and Short Form (MPQ, MPQ-SF) are commonly used to measure pain intensity (Figs. 11-4 and 11-5) (Herr, 2004). In addition, questions pertaining to pain duration, aggravating and relieving factors, and timing during the day and menstrual cycle are valuable. For example, if a woman notes the combination of dysmenorrhea, CPP, and dyspareunia, the risk of finding endometriosis at laparoscopy is threefold that in women with no symptoms (Fedele, 1992).

Psychosocial History

There is a significant association between physical, emotional, or sexual abuse and chronic pelvic pain (Bodden-Heidrich, 1999; Jamieson, 1997; Lampe, 2000). Additionally, for some women, chronic pain is an acceptable means to cope with social stresses. For these reasons, patients should be questioned about domestic violence and satisfaction with family relationships. Furthermore, an inventory of depressive symptoms is essential, as depression may cause or result from chronic pelvic pain (see Table 13-5).

PHYSICAL EXAMINATION

The etiology of chronic pain is varied and information gathered from physical examination can often clarify the source and direct further testing. In a woman with chronic pain, examination may be painful. For example, in those with neuropathic pain, mere light touch may elicit pain, which is termed *allodynia* . Therefore, the patient's ability to halt evaluation at any time should be understood. Examination should proceed slowly to allow relaxation between each step.

Stance and Gait

Women with intraperitoneal pathology may compensate with changes in posture, and such adjustments can create secondary musculoskeletal sources of pain (Musculoskeletal). Alternatively, musculoskeletal structures may be the site of referred pain from these organs (Table 11-4). Thus, orthopedic evaluation is integral in the evaluation of women with chronic pelvic pain.

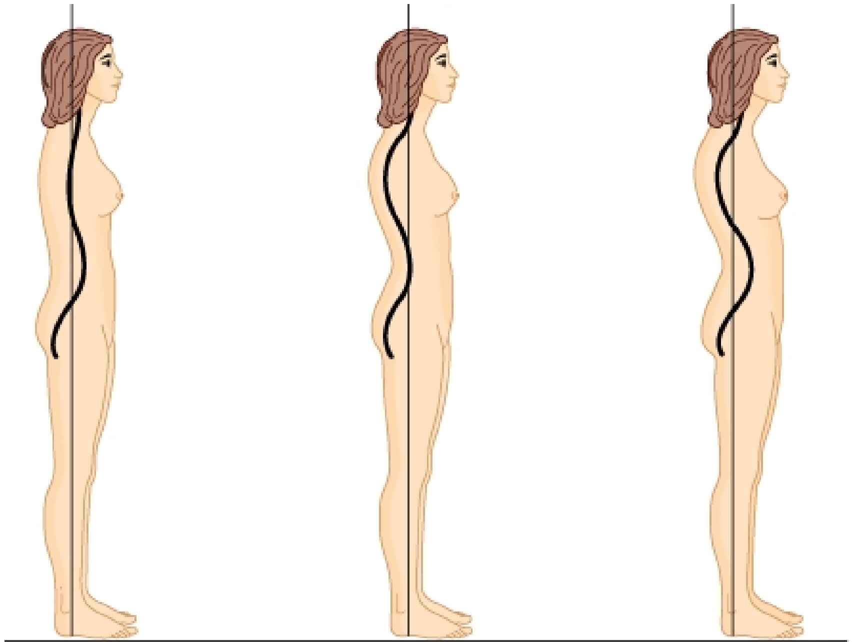
Initially, a woman is examined while standing. Posture should be evaluated anteriorly, posteriorly, and laterally. Posterior, inspection for scoliosis and levelness of the shoulders, gluteal folds, and knee creases is performed. Asymmetry may reflect musculoskeletal disorders.

Lateral visual examination may reveal lordosis and concomitant kyphosis, which has been noted in some women with CPP and termed *typical pelvic pain posture* (TPPP) (Fig. 11-6) (Baker, 1993). Abnormal tilt of the pelvic bones can be assessed by simultaneously placing an open palm on each side between the PSIS and anterior superior iliac spine (ASIS). Normally, the ASIS lies one-quarter inch below the level of the PSIS and greater distances may suggest abnormal tilt. Pelvic tilt may be associated with hip osteoarthritis and other orthopedic problems (Labelle, 2005; Yoshimoto, 2005).

FIGURE 11-6



Postural changes associated with lordosis and kyphosis-lordosis. TPPP = typical pelvic pain posture. *(From Howard, 2000, with permission.)*

Anterior inspection should focus on symmetry of the ASISs, umbilicus, and weight bearing. If one leg is dominant in weight bearing, the nonbearing leg is often externally rotated and slightly flexed at the knee. In addition to carriage, the anterior abdominal wall should additionally be inspected for signs of hernia (Fig. 11-7). Those that involve the anterior abdominal wall and pelvic floor are most commonly associated with CPP. Less frequently, *sciatic hernia,* which is herniation of peritoneum and peritoneal contents through the greater sciatic foramen, and *obturator hernia,* which is that through the obturator canal, have also been described sources of pain (Chang, 2005; Miklos, 1998; Moreno-Egea, 2006; Servant, 1998).

Mobility limitations may also be informative. A patient should be asked to bend forward at the waist. Limitation in forward flexion may reflect primary orthopedic disease or adaptive shortening of back extensor muscles, which is seen frequently in women with chronic pain and TPPP (Fig. 11-8). In such cases, patients are unable to create the normal convex curve with this motion.

Mobility testing. **A.** Normal flexion. **B.** Limited flexion may be seen in those with orthopedic disease or in those with chronic pelvic pain. *(From Baker, 1998, with permission.)*

Muscle weakness may also indicate orthopedic disease. A Trendelenburg test, in which a patient is asked to balance on one foot, can indicate dysfunction of hip abductor muscles or hip joint. With a positive test, when a woman elevates a leg by flexing the hip, the ipsilateral iliac crest droops (Fig. 11-9).

Trendelenburg test. **A.** In women without orthopedic disease, hip levels remain equal with leg lifting. **B.** Dropping of the nonweightbearing leg is a positive test and may indicate hip muscle or joint disease. *(From Baker, 1998, with permission.)*

Gait may also be evaluated. An *antalgic gait,* known as a limp, refers to a posture or gait that minimizes weight bearing on a lower limb or joint and indicates a higher probability of musculoskeletal pain.

Supine

The anterior abdominal wall should be evaluated for abdominal scars, which might serve as sites of hernia or nerve entrapment or may indicate intra-abdominal adhesive disease. Auscultation for bowel sounds and bruits should follow. Increased bowel activity may reflect irritable or inflammatory bowel diseases. Bruits should prompt investigation for vascular pathology.

While supine, a woman is asked to demonstrate with one finger the point of maximal pain and then encircle the total surrounding area of involvement. Superficial palpation of the anterior abdominal wall by a clinician may reveal sites of tenderness or knotted muscle that may reflect nerve entrapment or myofascial pain syndromes (Musculoskeletal). Moreover, pain with elevation of the head and shoulders while tensing the abdominal wall muscles, *Carnett sign,* is typical of anterior abdominal wall pathology. Tenderness originating from inside the abdominal cavity usually decreases with this test (Thomson, 1991). In addition, Valsalva maneuver during head and shoulder elevation may display diastasis of the rectus abdominis muscle or hernias. Diastasis recti can be differentiated in most cases from a ventral hernia. With diastasis, the borders of the rectus abdominis muscle can be palpated bilaterally along the entire length of the protrusion.

Deep palpation of the lower abdomen may identify pathology originating from pelvic viscera. Specifically, tenderness at the junction of the upper and middle thirds of a line drawn between the symphysis and anterior superior iliac spine may indicate pelvic congestion syndrome (Pelvic Congestion Syndrome). Dullness to percussion or a shifting fluid wave may reflect ascites.

Tests of mobility may give additional information. In most cases, a woman can elevate her leg 80Â° from the horizontal toward her head, termed a *straight leg test.* Pain with leg elevation may be seen with lumbar disk, hip joint, or myofascial pain syndromes. Additionally, symphyseal pain with this test may indicate laxity in the symphysis pubis or pelvic girdle. Both the obturator and iliopsoas tests may indicate myofascial pain syndromes involving these muscles or disorders of the hip joint. With the obturator test, a supine patient brings one thigh into 90Â° of flexion while the foot remains planted. The ankle is immobilized and the knee is gently pulled laterally and then medially to assess for tenderness. With the iliopsoas test, a supine woman attempts to flex each thigh separately against resistance from the examiner's hand. If pain is described with flexion, the test result is positive.

Sitting

A patient's posture in the sitting position should be inspected. Myofascial pain syndromes involving pelvic floor muscles often lead to patients shifting weight to one buttock or sitting toward a chair's front edge.

Lithotomy

Pelvic examination should begin with inspection of the vulva for generalized changes and localized lesions as outlined in Chapter 4. Specifically, erythema may reflect vulvitis or chronic fungal infection. Alternatively, thinning of vulvar skin may result from lichen sclerosus or atrophic changes.

After inspection, systematic pressure point palpation of the vulva is completed with a small cotton swab to map areas of pain (see Fig. 4-11). Palpation of the vagina ideally begins with one finger, which is gradually inserted 3 to 4 cm. Systematic sweeping pressure against the pelvic floor muscles along their length may identify isolated knots of taut muscle in those with myofascial pain syndrome of the pelvic floor. Typically, the pubococcygeus, iliococcygeus, and obturator intemus muscles can be reached with a vaginal finger (see Fig. 38-6). Additionally, tenderness of the urethra and bladder are potential indicators of urethral diverticulum or interstitial cystitis, respectively. Pain with deep palpation of the vaginal fornices may be seen with endometriosis, and cervical motion tenderness may be noted with PID. If pain follows gentle movement of the coccyx, then articular disease of the coccyx, termed *coccydynia,* is suspected.

Assessment of the uterus may reveal an enlarged uterus from leiomyomas, whereas enlargement with softening is more typical of adenomyosis. Immobility of the uterus may follow scarring from endometriosis, PID, malignancy, or adhesive disease from prior surgeries. Evaluation of the adnexa may reveal tenderness or mass. Such lateral tenderness may reflect endometriosis, diverticular disease, or pelvic congestion syndrome.

Rectal examination and rectovaginal palpation of the rectovaginal septum should be included. Palpation of hard stool or hemorrhoids may indicate GI disorders, whereas nodularity of the rectovaginal septum may be found with endometriosis or neoplasia. Myofascial tenderness involving the puborectalis and coccygeus muscles may be noted by sweeping the index finger with pressure across these muscles. Lastly, stool guaiac testing may be performed at the initial visit, or a woman may be sent home with serial guaiac testing cards to complete.

TESTING

Laboratory Evaluation

For women with chronic pelvic pain, diagnostic testing may add valuable information. Results from urinalysis and urine culture may indicate urinary tract stones, malignancy, or recurrent infection as sources of pain. Thyroid disease can affect physiologic functioning and may be found in those with bowel or bladder symptoms. Thus, serum thyroid-stimulating hormone (TSH) levels are commonly assayed. Diabetes can lead to neuropathy, and screening may be completed with urinalysis or serum evaluation.

Radiologic Imaging and Endoscopy

These modalities may be informative, and of these, transvaginal sonography is widely used by gynecologists to evaluate chronic pelvic pain. Sonography of the pelvic organs may reveal endometriomas, leiomyomas, ovarian cysts, and other structural lesions. However, despite its applicability for many gynecologic pathologies, sonography has poor sensitivity in identifying endometriotic implants or adhesions. Similarly, CT or MR imaging may be used, but often adds little additional information to that obtained with sonography.

In those with bowel symptoms, barium enema may indicate internal or external obstructive lesions, malignancy, and diverticular or inflammatory bowel disease. However, flexible sigmoidoscopy and colonoscopy may offer more information because colonic mucosa can be directly inspected and biopsied if necessary. In those in whom pelvic congestion syndrome is suspected, pelvic venography is the primary tool. This technique requires cannulation of the femoral vein to access the internal iliac vessels for contrast injection (Diagnosis).

Cystoscopy, laparoscopy, flexible sigmoidoscopy, and colonoscopy may each be employed, and patient symptoms will dictate their use. In those with symptoms of chronic pain and urinary symptoms, cystoscopy is typically advised. If gastrointestinal complaints are dominant, then flexible sigmoidoscopy or colonoscopy may be warranted. For many women with no obvious cause of their CPP, laparoscopy is performed, and approximately 40 percent of all gynecologic laparoscopies are performed for this indication (Howard, 1993). Importantly, intraoperative explanations for CPP are commonly found in those with normal preoperative examinations (Cunanan, 1983; Kang, 2007). Laparoscopy allows direct identification, and in many cases, treatment of intra-abdominal pathology.

One newer laparoscopic approach to CPP is performed under local anesthesia with the patient conscious and available for questioning regarding sites of pain (Howard, 2000; Swanton, 2006). Termed *conscious pain mapping,* this technique has resulted in improved postoperative pain scores but its clinical use to date has been limited.

TREATMENT

In many women with CPP, an identifying source is found and treatment is dictated by the diagnosis. However, in other cases, pathology may not be identified and treatment is directed toward dominant symptoms.

Analgesics

Treatment of pain typically begins with oral analgesics such as acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) (see Table 10-2). These are particularly helpful if inflammatory states underlie the pain.

If satisfactory relief is not achieved, then a mild opioid such as codeine or hydrocodone may be added to this regimen. Opioids are most effective and least addictive if given on a scheduled basis and at doses that adequately relieve pain (Table 39-15). If pain persists, stronger opioids such as morphine, methadone, fentanyl, oxycodone, and hydromorphone can replace milder ones. Close and regular surveillance is essential (Gunter, 2003).

Hormonal Suppression

Endometriosis is a common disorder found in women with CPP. Hormonal suppression may be considered, especially in those with co-existent dysmenorrhea or dyspareunia and who lack dominant bladder or bowel symptoms. As discussed in Chapter 10, Diagnostic Algorithm, combination oral contraceptives, progestins, gonadotropin-releasing hormone (GnRH) agonists, and certain androgens have proven effective.

Antidepressants and Anticonvulsants

For many, CPP represents neuropathic pain, and therapy has been extrapolated from treatment of such pain in other disorders. Tricyclic antidepressants have repeatedly been shown to reduce neuropathic pain independent of their antidepressant effects (Saarto, 2005). Moreover, antidepressants are a logical choice, as clinically significant depression is commonly comorbid with pain. Amitriptyline (Elavil) and its metabolite nortriptyline (Pamelor) have the best documented efficacy in the treatment of neuropathic and non-neuropathic pain syndromes (Table 11-5) (Bryson, 1996). Selective serotonin reuptake inhibitors do not appear to be as effective as tricyclic antidepressants (Gilron, 2006).

Table 11-5 Antidepressants and Antiepileptic Drugs Used in Chronic Pain Syndromes

Drug (Brand name)	Dosage	Side Effects
Antidepressants		

Tricyclic antidepressants		Dry mouth, constipation, urinary retention, sedation, weight gain
Amitriptyline (Elavil)[a]	For both, 10-25 mg at bedtime; increase by 10-25 mg per week up to 75-150 mg at bedtime or a therapeutic drug level	Tertiary amines have greater anticholinergic side effects
Imipramine (Tofranil)[a]		
Desipramine (Norpramin)[a]	For both, 25 mg in the morning or at bedtime; increase by 25 mg per week up to 150 mg per day or a therapeutic drug level	Secondary amines have fewer anticholinergic side effects
Nortriptyline (Pamelor)[a]		
Selective serotonin reuptake inhibitors		
Fluoxetine (Prozac)[a] Paroxetine (Paxil)[a]	For both, 10-20 mg per day; up to 80 mg per day for fibromyalgia	Nausea, sedation, decreased libido, sexual dysfunction, headache, weight gain
Novel antidepressants		
Bupropion (Wellbutrin)[a]	100 mg per day; increase by 100 mg per week up to 200 mg twice daily (400 mg per day)	Anxiety, insomnia or sedation, weight loss, seizures (at dosages above 450 mg per day)
Venlafaxine (Effexor)[a]	37.5 mg per day; increase by 37.5 mg per week up to 300 mg per day	Headache, nausea, sweating, sedation, hypertension, seizures Serotoninergic properties in dosages below 150 mg per day; mixed serotoninergic and noradrenergic properties in dosages above 150 mg per day
Antiepileptic drugs		
First-generation agents		
Carbamazepine (Tegretol)	200 mg per day; increase by 200 mg per week up to 400 mg three times daily (1200 mg per day)	Dizziness, diplopia, nausea, aplastic anemia
Phenytoin (Dilantin)[a]	100 mg at bedtime; increase weekly up to 500 mg at bedtime	Blood dyscrasias, hepatotoxicity
Second-generation agents		
Gabapentin (Neurontin)	100-300 mg at bedtime; increase by 100 mg every 3 days up to 1800 to 3600 mg per day taken in divided doses three times daily	Drowsiness, dizziness, fatigue, nausea, sedation, weight gain
Pregabalin (Lyrica)	150 mg at bedtime for diabetic neuropathy; 300 mg twice daily for postherpetic neuralgia	Drowsiness, dizziness, fatigue, nausea, sedation, weight gain

Lamotrigine (Lamictal)[a]	50 mg per day; increase by 50 mg every 2 weeks up to 400 mg per day	Dizziness, constipation, nausea; rarely, lifeâ€"threatening rashes

[a] Not approved by the U.S. Food and Drug Administration for treatment of neuropathic pain.

Abbreviated from Maizels, 2005, with permission.

In addition to antidepressants, anticonvulsants have also been used effectively in treatment of CPP. Of these, gabapentin and carbamazepine are most commonly used to reduce neuropathic pain (Wiffen, 2005a, 2005b).

Polypharmacy

Combining drugs with different sites or mechanisms of action may often increase pain relief. For example, an NSAID and an opioid may be partnered, especially in conditions in which inflammation is a dominant component. If muscle spasm underlies pain, then pairing a tranquilizer or a muscle relaxant with an opioid or an NSAID may improve results (Howard, 2003).

SURGERY

Neurolysis

Nerve destruction, termed *neurolysis,* involves nerve transection or injection of a neurotoxic chemical. Nerve transection cuts a specific peripheral nerve or may be performed on an entire nerve plexus.

Presacral neurectomy (PSN) describes interruption of somatic pain fibers from the uterus that course with the primarily sympathetic superior hypogastric plexus. This procedure is performed by incising the pelvic peritoneum over the sacrum and then identifying and transecting the sacral nerve plexus. Alternatively, laparoscopic uterosacral nerve ablation (LUNA) involves the destruction of the uterine nerve fibers that pass to the uterus through the uterosacral ligament. Most surgeons destroy approximately 2 cm of uterosacral ligament near its attachment to the uterus (Lifford, 2002). Based on pelvic innervation, these surgeries are indicated only for treatment of centrally located pelvic pain and have been performed to treat refractory endometriosis-related CPP and dysmenorrhea. In women so treated, approximately 75 percent note a greater than 50 percent decline in pain (American College of Obstetricians and Gynecologists, 2004).

Presacral neurectomy is technically challenging and requires familiarity with operating in the presacral space. Surgery has been associated with long-term constipation and urinary retention postoperatively. Infrequently, life-threatening hemorrhage from the middle sacral vessels may be encountered (Chap. 40, Presacral Venous Plexus).

Hysterectomy

For many women with CPP, especially that is related to organic pathologies, hysterectomy is effective in resolving pain and improving quality of life (Kjerulff, 2000; Stovall, 1990). However, for others, hysterectomy may fail to relieve CPP. This result may follow more commonly in those who are younger than 30 years or those who have depression, psychological problems, or no identifiable pelvic pathology (Gunter, 2003). Almost 40 percent of women with no identified pelvic pathology will have persistent pain post-hysterectomy (Hillis, 1995).

SPECIFIC CAUSES OF CHRONIC PELVIC PAIN

As noted earlier, endometriosis and leiomyomas are common causes of CPP and are discussed in detail in Chapters 9 and 10. Additional potential gynecologic sources of chronic pain include pelvic adhesive disease, ovarian remnant syndrome, and pelvic congestion.

Pelvic Adhesions

Adhesions are fibrous connections between opposing organ surfaces or between an organ and abdominal wall, at sites where there should be no connection. They vary in vascularity and thickness, and commonly are classified according to a system developed by the American Society of Reproductive Medicine (Table 11-6) (American Fertility Society, 1988). These fibrous connections are common, and in laparoscopies performed for CPP, adhesions are found in approximately one quarter of cases (Howard, 1993). However, not all adhesive disease creates pain. For example, Thornton and associates (1997) found no relationship between pelvic

pain and women with intra-abdominal adhesions.

Pathophysiology

The relationship between chronic pelvic pain and adhesions is incompletely understood. In those with CPP, intraperitoneal adhesions are believed to cause pain when they distort normal anatomy or when activities stretch the peritoneum or organ serosa. This theory is supported by studies using conscious pain mapping, in which filmy adhesions that allowed significant movement between two structures had the highest association with pain, whereas adhesions that prohibited movement had the lowest pain scores. Moreover, adhesions that had a relationship to the peritoneum had a high association with pain (Demco, 2004).

Diagnosis

Risks for adhesions include prior surgery, prior intra-abdominal infection, and endometriosis. Less commonly, inflammation from radiation, chemical irritation, or foreign-body reaction may be contributory. Pain is typically aggravated by sudden movement, intercourse, or other specific activities.

Laparoscopy is the primary tool used to diagnose adhesions. In general, sonography lacks sensitivity, but Guerriero and co-workers (1997) noted a positive correlation with ovarian adhesions if the ovarian surface borders appeared blurred or if the ovary appeared immediately adjacent to the uterus and this position persisted despite transducer manipulation.

Treatment

Surgical lysis is often used to treat pain symptoms, and a number of observational studies have shown pain improvement (Fayez, 1994; Steege 1991; Sutton 1990). However, two randomized studies comparing adhesion lysis with expectant management found no difference in pain scores after 1 year (Peters, 1992; Swank, 2003). In addition, adhesiolysis is associated with a significant risk of adhesiogenesis, especially in cases involving endometriosis (Parker, 2005). Thus, the decision to lyse adhesions should be individualized, and if lysis is performed, steps should be taken to minimize reformation (Hammoud, 2004). Gentle tissue handling, adequate hemostasis, and adhesion barriers have all been shown to be helpful.

Ovarian Remnant Syndrome and Ovarian Retention Syndrome

Following oophorectomy, remnants of an excised ovary may create symptoms that are termed *ovarian remnant syndrome.*

Distinction is made between this syndrome and *ovarian retention syndrome,* also known as *residual ovary syndrome,* which involves symptoms stemming from an ovary intentionally left at the time of previous gynecologic surgery (El Minawi, 1999). Although differentiated by the amount of ovarian tissue involved, both syndromes have nearly identical symptoms and are diagnosed and treated similarly.

Although an uncommon cause of CPP, women with symptomatic ovarian remnants most typically complain of chronic or cyclic pain or dyspareunia. The onset of symptoms is variable and may begin years following surgery (Nezhat, 2005).

Women with these syndromes may have a pelvic mass palpable on bimanual examination (Orford, 1996). Sonography is informative in many cases, and in those with ovarian remnants, ovaries may be identified, in some cases, by a thin rim of ovarian cortex surrounding a co-existent ovarian cyst (Fleischer, 1998). Indeterminate cases may require CT or MR imaging. In cases where ureteral compression is suspected, intravenous pyelography may be warranted. Additionally, laboratory testing, specifically FSH levels in reproductive-aged women with history of a bilateral oophorectomy, may aid diagnosis if these levels fall in premenopausal range (Magtibay, 2005).

Although medical treatment has included hormonal manipulation to suppress functioning tissue, surgical excision is required in most symptomatic cases (Lafferty, 1996). Because the ureter is commonly intimately involved with adhesions encasing a remnant, laparotomy is warranted in most cases. However, in those with advanced laparoscopic skills, successful outcomes have been documented (Nezhat, 2000, 2005).

Pelvic Congestion Syndrome

Retrograde flow through incompetent valves can often create tortuous, congested ovarian or pelvic veins. Chronic pelvic ache, pressure, and heaviness may result and is termed *pelvic congestion syndrome* (PCS) (Beard, 1988).

Pathophysiology

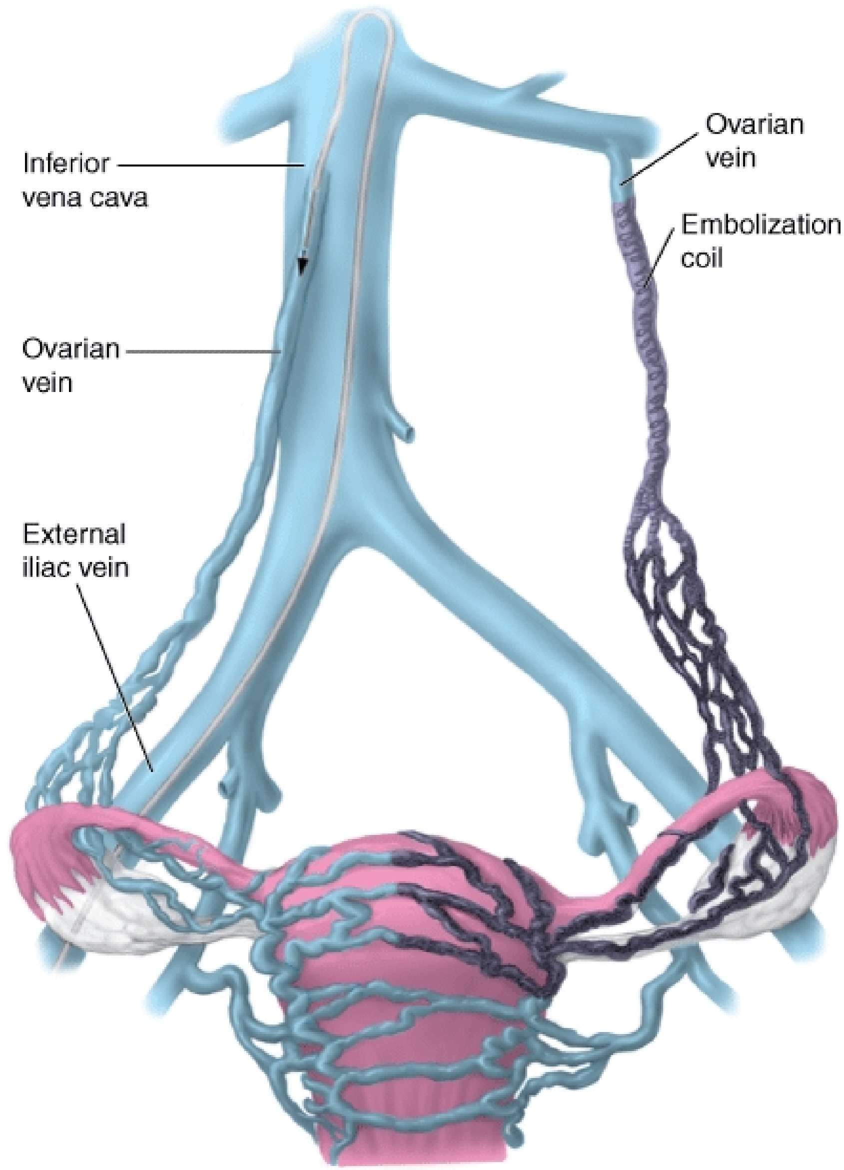
Currently, it is not clear whether congestion results from mechanical dilatation, ovarian hormonal dysfunction, or both. Higher rates of ovarian varicosities and PCS are noted in parous women. A mechanical theory describes a dramatic increase in pelvic vein diameter found in late pregnancy that leads to ovarian vein valve incompetence and pelvic varicosities. Additionally, estrogen has been implicated in PCS in that estrogen acts as a venous dilator. Moreover, PCS resolves following menopause, and anti-estrogenic medical therapy has been shown to be effective in these cases (Farquhar, 1989; Gangar, 1993). Most likely, both factors play roles. The cause of pain with pelvic congestion remains unclear, but increased dilatation, concomitant stasis, and release of local nociceptive mediators have been suggested (Giacchetto, 1989; Soysal, 2001).

Diagnosis

Affected women may describe pelvic ache or heaviness that may worsen premenstrually, after prolonged sitting or standing, or following intercourse. On physical examination, tenderness at the junction of the upper and middle thirds of a line drawn between the symphysis and anterior superior iliac spine or direct ovarian tenderness may be found. In addition, varicosities in the thigh, buttocks, perineum, or vagina may be associated (Venbrux, 1999).

The left ovarian venous plexus drains into the left ovarian vein, which empties into the left renal vein. The right ovarian vein generally drains directly into the inferior vena cava. Both ovarian veins may have numerous trunks (Fig. 11-10). Pelvic venography of this vascular anatomy is a primary diagnostic tool in women suspected of PCS, and embolization can be performed concurrently in identified candidates. Alternatively, CT, MR imaging, sonography, and diagnostic laparoscopy can identify varicosities. However, because these modalities are performed while a woman is prone, some varicosities may decompress and be missed (Park, 2004; Umeoka, 2004).

FIGURE 11-10



On the left, pelvic varices have already been treated with sclerosant and coils in the left ovarian vein. On the right, a guiding catheter is threaded into the right ovarian vein to perform ovarian venography and embolization. *(From Kim, 2006, with permission.)*

Treatment

Treatments for PCS have included chronic progestin or GnRH agonist administration, ovarian vein embolization or ligation, and hysterectomy with bilateral salpingo-oophorectomy (BSO), although none is definitive. For example, Beard and colleagues (1991) found that almost one third of women had some residual pain following total hysterectomy with BSO for this condition.

Embolization appears to afford effective treatment, and percentages of women with pain improvement range from 65 to 95 percent (Kim, 2006; Maleux, 2000; Venbrux, 2002). Chung and co-workers (2003) compared embolization against hysterectomy and oophorectomy and found embolization more effective. Long-term studies on its effects past 1 year, however, are lacking.

Alternatively, medical treatment with GnRH agonists (see Table 9-3) or medroxyprogesterone acetate, 30 mg orally daily, has been shown to be effective for some women with PCS, although symptoms typically recur after medication is discontinued (Reginald, 1989).

Dysmenorrhea

Cyclic pain with menstruation is common and accompanies most menses (Balbi, 2000; Weissman, 2004). This pain is classically described as cramping and is often accompanied by low backache, nausea and vomiting, headache, or diarrhea.

The term, *primary dysmenorrhea* , describes cyclic menstrual pain without an identifiable associated pathology, whereas *secondary dysmenorrhea* frequently complicates endometriosis, leiomyomas, PID, adenomyosis, endometrial polyps, and menstrual outlet obstruction. For this reason, secondary dysmenorrhea may be associated with other gynecologic symptoms, such as dyspareunia, dysuria, abnormal bleeding, or infertility.

Compared with secondary dysmenorrhea, primary dysmenorrhea more commonly begins shortly after menarche. Pain characteristics, however, typically fail to differentiate between the two types, and primary dysmenorrhea is usually diagnosed following exclusion of known associated causes.

RISKS FOR PRIMARY DYSMENORRHEA

When other factors are removed, primary dysmenorrhea equally affects women regardless of age, race, and socioeconomic status. However, increased pain duration or severity is positively associated with earlier age at menarche, long menstrual periods, smoking, and increased body mass index (BMI). In contrast, parity appears to improve symptoms (Harlow, 1996; Sundell, 1990).

PATHOPHYSIOLOGY

During endometrial sloughing, endometrial cells release prostaglandins as menstruation begins. Prostaglandins stimulate myometrial contractions and ischemia. Women with more severe dysmenorrhea have higher levels of prostaglandins in menstrual fluid, and these levels are highest during the first 2 days of menstruation. Prostaglandins are also implicated in secondary dysmenorrhea, however, anatomic mechanisms can also be identified, depending on the type of accompanying pelvic disease.

DIAGNOSIS

In women with menstrual cramps and no other associated findings or symptoms, no additional evaluation may be initially required, and empiric therapy may be prescribed (Proctor, 2006). In women at risk for PID, cultures for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are indicated. Moreover, if pelvic evaluation is incomplete due to body habitus, then transvaginal sonography may be informative to exclude structural pelvic pathology.

TREATMENT

Nonsteroidal Anti-Inflammatory Drugs

Because prostaglandins have been implicated in the genesis of dysmenorrhea, administration of NSAIDs is logical, and studies support their use (Marjoribanks, 2003; Zhang, 1998). These drugs and their dosages are found in Table 10-2.

Steroid Hormone Contraception

Combination hormone birth control methods are believed to improve dysmenorrhea by lowering prostaglandin production and observation studies of combination oral contraceptives (COCs) have noted improved dysmenorrhea in users (Brill, 1991; Gauthier, 1992; Hendrix, 2002; Milsom, 1990). In addition, extended or continuous administration of COCs may be useful in women with pain not controlled with traditional pill use (see Chap. 5, Estrogen Plus Progestin Contraceptives) (Sulak, 1997).

Progestin only contraceptives are also used to effectively treat dysmenorrhea. The levonorgestrel-releasing intrauterine system (LNG-IUS), depot medroxyprogesterone acetate injection, and progestin-releasing implanted rods have been shown to be effective in improving dysmenorrhea (see Chap. 5, Injectable Progestin Contraceptives) (Baldaszti, 2003; Varma, 2006).

Gonadotropin-Releasing Hormone Agonists and Androgens

The estrogen-lowering effects of these agents lead to endometrial atrophy and diminished prostaglandin production. Although

gonadotropin-releasing hormone agonists and androgens such as danazol have been shown to be effective in treating dysmenorrhea, their substantial side effects preclude their routine and long-term use. A fuller discussion and list of dosages for these agents and their side effects can be found in Chapter 9, GnRH Agonists.

Complementary and Alternative Medicine

Diet changes, herbal medicine, and physical treatments have each been sparsely evaluated in the treatment of dysmenorrhea. Oral vitamins E and B_1 (thiamine), magnesium, fish oil, low-fat diet, and the herb Toki-shakuyaku-san (TSS), have all been shown to improve dysmenorrhea, but evidence derives from small and typically nonrandomized trials (Barnard, 2000; Gokhale, 1996; Harel, 1996; Wilson, 2001; Ziaei, 2001). Additionally, data are limited but positive toward the use of exercise, topical heat, acupuncture, and transcutaneous electrical nerve stimulation (TENS) (Akin, 2001, 2004; Fugh-Berman, 2003; Golub, 1968; Helms, 1987; Kaplan, 1994).

Surgery

Cases of dysmenorrhea refractory to conservative management are unusual, and in such instances, surgery may be warranted. Hysterectomy is effective in treating dysmenorrhea, but may be unwanted in those desiring future fertility. For these women, LUNA or presacral neurectomy may be indicated (Neurolysis). There is limited evidence to support the use of surgery for primary dysmenorrhea, but comparisons of LUNA and presacral neurectomy show significantly greater long-term pain relief with presacral neurectomy (Proctor, 2005).

Dyspareunia

Dyspareunia is a frequent gynecologic complaint and in reproductive-aged U.S. women, the 12-month prevalence is noted to be 15 to 20 percent (Glatt, 1990; Laumann, 1999). Painful intercourse may be associated with vulvar, visceral, musculoskeletal, neurogenic, or psychosomatic disorders. Moreover, co-existent etiologies may lead to similar symptoms. For example, women with vulvodynia have been shown in many cases to have co-existent pelvic floor muscle spasm, both of which may cause dyspareunia (Reissing, 2005). Because of the frequent association between dyspareunia and CPP and frequent overlap of etiologies, physical examination and diagnostic testing often follow that for women with CPP (Physical Examination).

Dyspareunia may be subclassified as *insertional,* that is, pain with vaginal entry, or *deep* , which is associated with deep thrusting. Vulvodynia, vulvitis, and poor lubrication comprise the bulk of insertional dyspareunia, whereas endometriosis, pelvic adhesions, and bulky leiomyomas are frequent causes of deep dyspareunia. However, in many women, both insertional and thrust dyspareunia may be present.

Additional terms include *primary dyspareunia* and *secondary dyspareunia,* which describe the onset of pain coincident with coitarche or after a period of pain-free intercourse, respectively. Although sexual abuse, female genital mutilation, and congenital anomalies most frequently lead to primary dyspareunia, sources of secondary dyspareunia are more varied. Lastly, dyspareunia should be clarified as *generalized,* occurring in all episodes of intercourse or as *situational,* associated with only specific partners or sexual positions.

DIAGNOSIS

History taking in women with dyspareunia should include questions about associated symptoms such as vaginal discharge, vulvar pain, dysmenorrhea, CPP, or scant lubrication. Onset of symptoms and other associated events such as obstetric delivery, pelvic surgery, or sexual abuse is often informative. In addition, dyspareunia may be found in those who breast feed, presumably because of hypoestrogenism seen with lactation (Buhling, 2006; Signorello, 2001). Psychosocial topics such as relationship satisfaction or depression should also be covered.

Inspection of the vulva should follow that for chronic pain. In particular, generalized erythema, episiotomy scars, or atrophy is sought. Erythema may indicate contact or allergic dermatitis or infection, particularly fungal infection (Chap. 4). Accordingly, a historical inventory of potential skin irritants, a saline slide preparation, vaginal pH testing, and vaginal cultures are performed. Specifically, a vaginal fungal culture may be required in some cases because several noncandidal species may be difficult to detect with only microscopic analysis (Edwards, 2003; Haefner, 2005).

Some, but not all, have found a positive correlation between degree of pelvic organ prolapse and dyspareunia (Burrows, 2004; Ellerkmann, 2001). If noted, its degree should be assessed with pelvic organ prolapse evaluation (POP-Q) (see Chap. 24, Pelvic Organ Prolapse Quantification (POP-Q)).

Physical examination may begin with palpation of the Bartholin and periurethral glands. Additionally, cotton swab testing is used to map painful areas (see Fig. 4-11). Insertion of a single digit into the vagina may elicit *vaginismus,* that is, reflex contraction of the muscles associated with distal vaginal penetration (Basson, 2000). Spasm is thought to be a conditioned response to a current or former physical pain, and the bulbocavernosus, pubococcygeus, piriformis, and obturator internus muscles are most typically involved (Bachmann, 1998).

With deeper insertion, digital examination may trigger midvaginal pain, which may be seen with interstitial cystitis, congenital anomalies, or following radiation therapy or pelvic reconstructive surgeries.

Etiologies of deep dyspareunia more commonly mirror those for CPP and focal points of examination are discussed on page 253. Similarly, diagnostic testing in great part mirrors that for CPP. Urine and vaginal cultures may indicate infection, and radiologic imaging may reveal structural visceral disease.

TREATMENT

Resolution of dyspareunia is highly dependent on the underlying cause. For those with vaginismus, structured desensitization is effective. Patients gradually gain control in comfortably inserting dilators of increasing size into the introitus. Concurrent psychological counseling in such cases is often warranted. Poor lubrication may be countered with education directed toward adequate arousal techniques and use of external lubricants.

Surgery may be indicated for structural pathologies and may include ablation of endometriosis, lysis of adhesions, and restoration of normal anatomy in cases of congenital anomalies or female genital mutilation (Nour, 2006). For those with dyspareunia related to a retroverted uterine position, uterine suspension has been shown, although in small studies, to be effective (Perry, 2005).

Dysuria

Evaluation of dysuria begins with a careful pelvic inspection to exclude vaginitis, vulvar lesions, and urethral diverticulum. A voiding diary can be informative, and for those with associated dyspareunia, a sexual inventory should be obtained. The most common cause of dysuria is infection, and urinalysis and urine culture are therefore initial tests (see Chap. 3, Diagnosis). Similarly, *Chlamydia trachomatis* and herpes simplex virus infections should be excluded. For those with chronic dysuria, urodynamic studies may help to identify those with detrusor overactivity, significantly decreased compliance, or bladder outlet obstruction (see Chap. 23, Diagnostic Testing). Cystoscopy is used to identify the hallmark mucosal findings of interstitial cystitis and exclude neoplastic growths or stones (Irwin, 2005). Adjunctively, sonography or laparoscopy may be indicated to exclude structural pelvic pathology or endometriosis.

INTERSTITIAL CYSTITIS

This chronic inflammatory disorder of the bladder is typified by symptoms of frequency, urgency, and pelvic pain (Bogart, 2007). With interstitial cystitis (IC), this triad is found in combination with characteristic mucosal changes and reduced bladder capacity (Hanno, 1994). Cystoscopically, *Hunner ulcers* are reddish-brown mucosal lesions with small vessels radiating toward a central scar and are found in approximately 10 percent of cases (Fig. 11-11) (Messing, 1978; Nigro, 1997). The other more common finding is *glomerulations,* which are small petechiae or submucosal hemorrhages.

FIGURE 11-11

In addition to women with classic IC findings, the International Continence Society (ICS) has created an additional category to describe those with chronic IC symptoms, but who lack cystoscopic findings. *Painful bladder syndrome* describes symptoms of IC but in the absence of proven urinary infection or other obvious pathology (Abrams, 2002).

Prevalence

The prevalence of IC in the United States is variable and cited at 30 to 60 per 100,000 (Curhan, 1999; Jones, 1997). It is diagnosed more commonly in women, in Caucasians, in smokers, and in those in their 40s (Kennedy, 2006; Propert, 2000). In addition, IC is seen in association with irritable bowel syndrome, generalized pain disorders, fibromyalgia, pelvic floor dysfunction, and depression (Aaron, 2000; Clauw, 1997; Novi, 2005; Peters, 2007).

Pathophysiology

The exact cause of IC is not known, and current theories include increased mucosal permeability or mast cell activation (Sant, 2007; Warren, 2002). Glycosaminoglycans are an important component of the mucin layer that covers and protects the bladder urothelium. One theory explains that IC symptoms originate from an increased bladder mucosa permeability that results from a defect in the protective bladder glycosaminoglycan component (Parsons, 2003).

Diagnosis

Koziol (1994) reported symptoms in a series of IC sufferers and found frequency, urgency, and pelvic pain to be most common.

Frequency occurs both in the day and night, and voiding events average 16 times per day but can reach 40 times daily. Pain is described as vaginal, suprapubic, or lower abdominal and often worsens during the week before menstruation. It is commonly exacerbated by spicy foods; alcoholic, acidic, carbonated, and caffeinated beverages; and by coitus, stress, and exercise. Pain is often relieved with voiding small amounts of urine, but typically recurs as the bladder refills. Additionally, women commonly describe dyspareunia (Metts, 2001).

Many other conditions can produce similar symptoms to IC, and most urologists have therefore regarded IC as being a diagnosis of exclusion. Accordingly, patients suspected of having IC typically undergo cystoscopy. Bladder biopsy is not required to diagnose IC, but biopsies are often performed to exclude other bladder pathology such as cancer. Urodynamic testing is recommended in those with urgency. In women with IC, both bladder capacity and compliance are decreased.

Treatment

Interstitial cystitis is a chronic disorder with exacerbations and remissions. There is no universally accepted therapy, and for some, expectant management is appropriate. Of therapies, hydrodistention, amitriptyline, bladder analgesics, dietary restriction, and intravesical heparin or pentosanpolysulfate are among the more commonly used (Rovner, 2000). The Interstitial Cystitis Association serves as an important resource to patients and clinicians for therapy options and other needs (http://www.ichelp.org).

GASTROINTESTINAL DISEASE

In a significant number of cases, gastrointestinal disease is found as an underlying cause of chronic pelvic pain. Zondervan and associates (1999) followed a cohort of women with CPP and found that irritable bowel syndrome and interstitial cystitis were the most common diagnoses. As seen in Table 11-1, GI causes may be organic or functional. Symptoms such as fever, gastrointestinal bleeding, weight loss, anemia, and abdominal mass should prompt evaluation for organic pathology. Initial screening may follow that for CPP, but for those with diarrheal states, additional stool examination for leukocytes or ova and parasites may be indicated. Investigations may include a sigmoidoscopy or colonoscopy to exclude inflammation or tumors. When indicated, sonography may aid in distinguishing gastrointestinal from gynecologic pathology.

Functional Bowel Disorders

Also known as *functional gastrointestinal disorders* (FGIDs), this group of functional disorders has symptoms attributable to the lower GI tract and includes those listed in Table 11-7. In defining these chronic conditions, symptoms must have begun more than 6 months previously and have occurred more than 3 days a month during the last 3 months (Longstreth, 2006). The diagnosis always presumes the absence of a structural or biochemical explanation for symptoms (Thompson, 1999).

Table 11-7 Functional Gastrointestinal (GI) Disorders

Functional bowel disorders	
Irritable bowel syndrome (IBS)	Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with 2 or more of the following: (1) improved with defecation; (2) onset associated with a change in stooling frequency; (3) onset associated with a change in form of stool
Functional abdominal bloating	Must include *both* of the following: (1) recurrent feeling of bloating or visible distention at least 3 days/month in 3 months; (2) insufficient criteria for a diagnosis of functional dyspepsia, IBS, or other functional GI disorder
Functional constipation	Must include *two or more* of the following: (1) straining during at least 25% of defecations; (2) lumpy or hard stools in at least 25% of defecations; (3) sensation of incomplete evacuation for at least 25% of defecations; (4) sensation of anorectal obstruction/blockage for at least 25% of defecations; (5) manual maneuvers to aid at least 25% of defecations; (6) fewer than three defecations per week Loose stools are rarely present without the use of laxatives There are insufficient criteria for IBS
Functional diarrhea	Loose or watery stools without pain, occurring in at least 75% of stools
Unspecified functional bowel disorder	Bowel symptoms not attributable to an organic etiology that do not meet criteria for the previously defined categories
Functional abdominal pain	
Functional abdominal pain	At least 6 months of: (1) continuous or nearly continuous abdominal pain; and (2) no or only occasional relation of pain with physiologic events (e.g., eating, defecation, or menses); (3) some loss of daily functioning; (4) pain is not feigned (e.g., malingering); (5) insufficient criteria for other functional gastrointestinal disorders that would explain the abdominal pain
Unspecified functional abdominal pain

IRRITABLE BOWEL SYNDROME

Definition and Incidence

This functional bowel disorder is defined as abdominal pain or discomfort with defecation or with a change in bowel habits. Subtypes are divided by the predominant stool pattern and include constipative, diarrheal, and mixed stool categories. Although defining criteria are listed in Table 11-7, other symptoms that may support the diagnosis include abnormal stool frequency (fewer than three bowel movements per week or more than three per day), abnormal stool form, straining, urgency, passing mucus, and bloating (Longstreth, 2006).

Irritable bowel syndrome (IBS) is common, and its prevalence in the general population is estimated to be near 10 percent. The prevalences of diarrhea-predominant and constipation-predominant IBS are equivalent and both are approximately 5 percent (Saito, 2002).

Pathophysiology

With IBS, neural, hormonal, genetic, environmental, and psychosocial factors are variably involved (Drossman, 2002). The primary pathophysiologic mechanism of IBS, however, is thought to involve dysregulation in interactions between the central nervous system (CNS) and enteric nervous system (ENS). Such brain-gut dysfunction may eventually cause alterations of gastrointestinal mucosal immune response, intestinal motility and permeability, and visceral sensitivity. These in turn produce abdominal pain and altered bowel function (Harris, 2006). Specifically, serotonin (5-hydroxytryptamine, 5-HT) is involved with regulating intestinal motility, visceral sensitivity, and gut secretion and is thought to play an important role in IBS (Atkinson, 2006; Gershon, 2005).

Diagnosis

Organic diseases such as those in Table 11-1 are excluded prior to the diagnosis of IBS, although for patients who have typical IBS symptoms and no symptoms of organic disease, few tests are required. Testing is based on a patient's age, duration and severity of symptoms, psychosocial factors, presence of organic disease symptoms, and family history of gastrointestinal disease.

TREATMENT

Diet

Traditionally, therapy to increase daily fiber intake has been used. Although dietary fiber is effective in treating constipation, it has not been shown to be effective for diarrhea-dominant cases of IBS or for IBS-associated pain (Quartero, 2005). Management of food intolerances can be another potentially valuable treatment adjunct (Alpers, 2006).

Medications

In general, drug therapy is directed toward dominant symptoms (Fig. 11-12). For those with constipation-dominant IBS, commercial fiber analogs may help if increased dietary fiber is unsuccessful (Table 11-8) (Ramkumar, 2005). In addition, stimulation of the serotonin receptor subtype 5-hydroxytryptamine-4 (5-HT$_4$) increases colonic transit time and inhibits visceral sensitivity. Specifically, tegaserod (Zelnorm, Novartis, East Hanover, NJ), a partial 5-HT$_4$ receptor agonist, increases colonic motility and has been effective in relief of constipation-predominant IBS (Layer, 2005; Tack, 2005). However, in 2007, Novartis suspended U.S. sales of Zelnorm in compliance with a request by the Food and Drug Administration (FDA). An increased incidence of cardiovascular events in those using this agent prompt the FDA's action.

Table 11-8 Agents Used to Treat Irritable Bowel Syndrome (IBS)

Symptom	Drug	Oral Dosage
Diarrhea	Loperamide	2â€“4 mg when necessary; maximum 12 g/d
	Cholestyramine resin	4 g with meals
	Alosetron	0.5â€“1 mg bid (for severe IBS)
Constipation	Psyllium husk	3.4 g bid with meals, then adjust
	Methylcellulose	2 g bid with meals, then adjust
	Calcium polycarbophil	1 g qd to qid
	Lactulose syrup	10â€“20 g bid
	70% sorbitol	15 mL bid
	Polyethylene glycol 3350	17 g in 8 oz. water qd
	Magnesium hydroxide	2â€“4 tbsp qd
Abdominal pain	Tricyclic antidepressants	Start at 25â€“50 mg hs, then adjust

	Selective serotonin reuptake inhibitors	Begin with a small dose and increase as needed

bid = twice daily; hs = at bedtime; qd = daily, qid = four times daily.

For those with diarrhea-dominant symptoms, loperamide (Imodium, McNeil PPC, Fort Washington, PA) or diphenoxylate (Lomotil, Pfizer, New York, NY) are effective in slowing bowel motility. As substances stay longer in the intestine, more water is absorbed from fecal matter. Thus, for those with severe diarrhea, alosetron (Lotronex, GlaxoSmithKline, Philadelphia, PA), a selective serotonin 5-HT_3 receptor antagonist, interacts with receptors of enteric nervous system neurons to decrease pain, urgency, and stool frequency (Camilleri, 2000; Chey, 2004).

For patients with pain, antispasmodic agents decrease intestinal smooth muscle activity and are thought to decrease abdominal discomfort if pain is secondary to spasm. Agents available in the U.S. include dicyclomine (Bentyl) and hyoscyamine (Levsin). In general, these agents are safe, inexpensive, and have been shown to be effective (Quartero, 2005). However, evidence-based data supporting their use are small, and anticholinergic side effects of these agents often limit their long-term use (Schoenfeld, 2005).

Tricyclic antidepressants may help patients with IBS both by an anticholinergic effect on the gut and mood-modifying action. Tricyclic antidepressants may slow intestinal transit time and have been shown to be effective in treatment of diarrhea-dominant IBS (Hadley, 2005). Alternatively, another class of antidepressant, the selective serotonin reuptake inhibitors (SSRIs), has been shown in small studies to be useful for irritable bowel syndrome (Tabas, 2004; Vahedi, 2005).

Psychological Therapy

Psychological or behavioral treatments may help some patients. Of these, cognitive-behavioral therapy and hypnotherapy have been shown to be effective (Drossman, 2003; Gonsalkorale, 2003; Payne, 1995).

MUSCULOSKELETAL

In the search for visceral sources of pelvic pain, the evaluation for musculoskeletal disorders is sometimes minimized by gynecologists. Yet potential causes are numerous.

Myofascial Pain Syndrome

A hyperirritable area within a muscle can lead to persistently contracted fibers and cause pain, weakness, or autonomic reactions (Simons, 1999). The primary reactive area within the muscle is termed a *trigger point* (TrP) and is identified as a palpable taut, ropy band. Myofascial trigger points can affect any muscle, and those involving muscles of the anterior abdominal wall, pelvic floor, and pelvic girdle can be sources of chronic pelvic pain. For this reason, the American College of Obstetricians and Gynecologists (1988) recommends an assessment of the musculoskeletal system prior to laparoscopy or hysterectomy for CPP.

PATHOPHYSIOLOGY

Trigger points are thought to form as the end of a metabolic crisis within a muscle. Dysfunction of a neuromuscular endplate can lead to sustained acetylcholine release, persistent depolarization and sarcomere shortening, and creation of a taut muscle band. Affected fibers compress capillaries and decrease local blood flow. The resulting ischemia leads to release of substances that activate peripheral nerve nociceptors, and in turn cause pain (McPartland, 2004).

A persistent barrage of nociceptive signals from TrPs may eventually lead to central sensitization and the potential for neuropathic pain (Neuropathic Pain). Signals may spread segmentally within the spinal cord to cause localized or referred pain (Gerwin, 2005). Trigger points can also initiate somatovisceral responses such as vomiting, diarrhea, and bladder spasm, which may add confusion to the diagnosis.

INCIDENCE AND RISK FACTORS

The incidence of myofascial disease is unknown, but in an evaluation of 500 patients with chronic pelvic pain, Carter (1998) found 7 percent of patients primarily had trigger points as a source of their pain. Prevalence appears to be greatest in those between 30 and 50 years of age. Risk factors are varied, although many trigger points can be traced to a prior specific trauma such as a sporting injury or to chronic biomechanical overload of a muscle (Sharp, 2003). Accordingly, in evaluating patients with chronic pain and suspected myofascial pain syndrome (MPS), a detailed inventory of sporting injuries, traumatic injuries, surgeries, and work activities is essential.

DIAGNOSIS

Patients typically describe the pain as aggravated by specific movement or activity and relieved by certain positions. Pressure on a TrP and cold, damp exposure generally worsens pain.

During examination, flat palpation, pincer palpation, and deep palpation may each be required, depending on muscle location, to locate a Trp. Flat palpation uses fingertips to roll over superficial muscles that have only one surface available. In those muscles with greater accessibility, pincer palpation grasps the muscle belly between the thumb and fingers. Finally, digital probing is required for deep muscles. In those with MPS, spot tenderness and taut muscle bands are appreciated. Classically, the involved muscle displays weakness and restricted stretch. Additionally, TrP pressure may also elicit a local muscle twitch response or reproduce a patient's referred pain or both.

MUSCLE GROUPS

Identification by the patient of painful sites on a pain diagram can be an informative first step (see Fig. 11-5). Involvement of specific muscles will often give characteristic patterns (Fig. 11-13).

Drawing illustrates that anterior abdominal wall muscle trigger points can create extensive patterns of referred pain. Asterisks are trigger points. Dark and light stippling reflect varying patterns of referred pain. *(From Costello, 1998, with permission.)*

Abdominal Wall Muscles

Rectus abdominis, the obliques, and transversus abdominis muscles may all develop TrPs that lead to CPP. Associated somatovisceral pelvic symptoms from these muscles may include diarrhea or urinary frequency, urgency, or retention.

Painful TrPs are frequently found along the lateral margin of the rectus abdominis muscles, termed the linea semilunaris (Suleiman,

2001). Additionally, TrPs in the rectus abdominis muscle commonly develop below the umbilicus and at the muscle's insertion into the pubic bone. Trigger points of the external oblique frequently involve its lateral attachment to the anterior iliac crest and pain usually refers to the pubic bone.

Pelvic Floor Muscles

Trigger points involving the levator ani, coccygeus, and anal sphincter muscles are frequently associated with poorly localized pain that may be described as involving the coccyx, hip, or back (Fig. 11-14). Dyspareunia is common. Palpation of these muscles for TrPs mirrors that described earlier in the examination for chronic pelvic pain (Abdominal Examination).

Pain stemming from TrPs involving the levator ani muscles has had a variety of names including *levator ani spasm syndrome* and *coccydynia.* Currently, *levator ani syndrome* is the preferred term and coccydynia is reserved for coccygeal pain originating from skeletal trauma to the coccyx.

Perineal Muscles

The superficial transverse perineal, bulbocavernosus, and ischiocavernosus muscles can be assessed with flat palpation for TrPs.

Pelvic Wall Muscles

Trigger points involving the obturator internus muscle may lead to vaginal, anal, coccygeal, or posterior thigh pain. With the patient supine and hip straight, medial rotation may be limited.

Additionally, patients may have involvement of muscles that support the pelvic bones. In general, TrPs within the gluteus muscles, piriformis, and iliopsoas will have additional referred pain to the groin or buttock or both.

TREATMENT

The goal of treatment is inactivation of trigger points, which then allows stretching and release of taut muscle bands. Therapies are varied and include, among others: TrP release maneuvers, biofeedback, TrP dry needling or injection, local heat, and pharmacologic agents such as NSAIDs, other analgesics, muscle relaxants, and tranquilizers.

NEUROLOGIC

Nerve Entrapment

Anterior abdominal wall pain is frequently mistaken for visceral pain, and common causes include nerve entrapment of the anterior cutaneous branches of the intercostal, ilioinguinal, iliohypogastric, genitofemoral nerves, and lateral femoral cutaneous nerve branches (Greenbaum, 1994).

Alternatively, exertion-related swelling of the piriformis muscle, termed *piriformis syndrome,* may lead to buttock and posterior leg pain in the distribution of the sciatic nerve (Broadhurst, 2007; Fishman, 2002). Nerve entrapment neuropathies of the pudendal nerve may lead to perineal pain or fecal incontinence (Gooneratne, 2007).

PATHOPHYSIOLOGY

Peripheral nerves may be compressed either within narrow anatomic canals or rings, or beneath tight ligaments, fibrous bands, or sutures. Thus, common sites of compression for a given nerve are often predictable based on their anatomy.

Each anterior cutaneous branch of the intercostal nerves traverses anteriorly through the rectus abdominis muscle. Each branch and its corresponding vessels travels through a fibrous ring found within the lateral aspect of rectus abdominis muscle and medial to the linea semilunaris (Fig. 11-15). On crossing the anterior rectus sheath, each branch divides and then courses within the subcutaneous tissues. Fat surrounding the neurovascular bundle appears to pad the enclosed structures within the fibrous ring (Srinivasan, 2002). However, if this bundle receives excessive intra- or extra-abdominal pressure, compression of the bundle against the fibrous ring causes nerve ischemia and pain (Applegate, 1997).

Drawing displays anterior abdominal cutaneous nerve entrapment. *(Redrawn from Greenbaum, 1994, with permission.)*

Alternatively, nerve entrapment, injury, or neuroma formation involving branches of the ilioinguinal, iliohypogastric, lateral femoral cutaneous nerve or genitofemoral nerves may follow inguinal hernia repair, low transverse abdominal incisions such as a Pfannenstiel incision, and lower abdominal incisions for laparoscopic trocar placement (see Section 41-2, Pfannenstiel Incision and Section 41-28, Laparoscopy). Hypoesthesia is the more common finding with these injuries, but pain may variably develop within months of surgery or after several years.

DIAGNOSIS AND TREATMENT

Criteria for diagnosing nerve entrapment are clinical and include: (1) pain aggravated by patient movement or light skin pinching over the affected area and (2) pain improvement following local anesthetic injection. In general, electromyography is not useful because it lacks adequate sensitivity (Knockaert, 1996).

In addition to physical examination, local injection of anesthetic agents with or without corticosteroids in most cases will improve pain. One- or 2-percent lidocaine and a 40 mg/mL concentration of triamcinolone can be combined in a 1:1 ratio. Less than half a milliliter is injected at each site. Additional treatments may include oral analgesics, biofeedback, and gabapentin. If conservative options fail to bring sufficient relief, neurolysis with injection of 5- to 6-percent absolute alcohol or phenol or surgical neurectomy may be required (Madura, 2005; Suleiman, 2001).

BREAST DISEASE: INTRODUCTION

Breast disease in women encompasses a spectrum of benign and malignant disorders, which present most commonly as breast pain, nipple discharge, or palpable mass. The specific causes of these symptoms vary with patient age. Benign disorders predominate in young premenopausal women, whereas malignancy rates increase with advancing age. Evaluation of breast disorders usually requires the combination of a careful history, physical examination, imaging, and when indicated, biopsy.

ANATOMY

Ductal System

The glandular portion of the breast is comprised of 12 to 15 independent ductal systems that each drain about 40 lobules (Fig. 12-1). Each lobule consists of 10 to 100 milk-producing acini that drain into small terminal ducts (Parks, 1959). Terminal ducts drain into larger collecting ducts that merge into even larger ducts, which exhibit a saccular dilation just below the nipple called a lactiferous sinus (Fig. 12-2).

In general, only six to eight openings are visible on the nipple surface. These drain the dominant ductal systems, which account for about 80 percent of the breast's glandular volume (Going, 2004). Minor ducts either terminate just below the nipple surface or open on the areola near the base of the nipple. The areola itself contains numerous lubricating sebaceous glands, called Montgomery glands, which are often visible as punctate prominences.

In addition to epithelial structures, the breast is composed of varying proportions of collagenous stroma and fat. The distribution and abundance of these stromal components accounts for a breast's consistency when palpated and for its imaging characteristics.

Lymphatic Drainage

Afferent lymphatic drainage of the breast is provided by dermal, subdermal, interlobar, and prepectoral systems (Fig. 12-3) (Grant, 1953). Each of these may be viewed as a lattice of valveless channels that interconnect with every other system and that ultimately drain into one or two axillary lymph nodes (the sentinel nodes). Because all of these systems are interconnected, the breast drains as a unit, and injection of colloidal dyes in any part of the breast at any level will result in accumulation of dye in the same one or two axillary sentinel lymph nodes. The axillary lymph nodes receive most of the lymphatic drainage of the breast, and consequently are the nodes most frequently involved with breast cancer metastases (Hultborn, 1955). However, there are also alternative drainage pathways that do not appear to interconnect with other networks and that drain directly into internal mammary, supraclavicular, contralateral axillary, or abdominal lymph node basins.

DEVELOPMENT AND PHYSIOLOGY

During fetal development, the primordial breast arises from the basal layer of the epidermis. Before puberty, the breast is a rudimentary bud comprised of a few branching ducts capped with alveolar buds, end buds, or small lobules (Osin, 1998). At puberty, usually between the ages of 10 and 13 years, ovarian estrogen and progesterone cooperate to direct organized communication between breast epithelial cells and mesenchymal cells, resulting in extensive branching of the ductal system and development of lobules (Ismail, 2003). Specific disorders of this development are discussed in Chapter 14, Breast Development and Disease. Final differentiation of the breast is mediated by progesterone and prolactin and is not completed until the first full-term pregnancy (Grimm, 2002; Ismail, 2003).

During the reproductive years, terminal ducts near the acini and the acini themselves are most sensitive to ovarian hormones and prolactin. Most forms of benign and malignant breast disease arise in these terminal duct-acinar structures. Breast epithelial cells proliferate during the luteal phase of the menstrual cycle when estrogen and progesterone levels are increased, and then undergo programmed cell death at the end of the luteal phase, when levels of these hormones decline (Anderson, 1982; Soderqvist, 1997). This effect is mediated by paracrine signaling induced by estrogen receptor activation and is associated with an increase in the water content of the extracellular matrix (Stoeckelhuber, 2002). This is often recognized as breast fullness and tenderness the week preceding menses.

At menopause, when ovarian estrogen production ceases, breast lobules involute, and the collagenous stroma is replaced by fat. Because estrogen receptor expression is negatively regulated by estrogen, there is an increase in estrogen receptor expression after menopause (Khan, 1997). Despite a decline in ovarian estrogen production, postmenopausal women continue to produce estrogen through the action of the enzyme aromatase, which converts adrenal androgens to estrogen (Bulun, 1994). Aromatase is found in fat, muscle, and breast tissue.

EVALUATION OF A BREAST LUMP

It is not possible to distinguish benign from malignant or cystic from solid breast masses by clinical examination. However, findings from clinical examination, interpreted in conjunction with imaging and pathology (the triple test), contribute significantly to management decisions (Hermansen, 1987).

Physical Examination

The breast is comma shaped, and the comma's tail corresponds to the axillary tail of Spence. This extension can be large, especially during pregnancy and lactation, and is frequently mistaken for an axillary mass.

Clinical examination of the breast begins with inspection of the breast to determine whether there is dimpling, nipple retraction, or skin changes. This examination is described further in Chapter 1. The presence and character of expressible nipple discharge is recorded. In addition, the location of a mass is specifically documented according to its clock position and then measured along the long axis using a ruler or caliper (Fig. 12-4). The distance from the center of the nipple to the center of the mass is specified. Since many health care providers are typically involved in the evaluation and management of the same breast mass, the most useful entry in the clinical record will define the location and size of the mass (e.g., right breast, 2-cm mass, 3:00, 4 cm from the nipple). Although clinical examination alone can never exclude malignancy, noting that a mass has benign features such as smoothness, roundness, and mobility will factor into the ultimate decision to excise or observe a lesion. Evaluation should also include careful examination of the axillae, infraclavicular fossa, and supraclavicular fossa (see Chap. 1, Lymph Node Evaluation).

Recording the location of a breast mass as "Left breast, 2.5-cm mass, 2:00, 6 cm FN". FN = from the nipple.

Diagnostic Imaging

Diagnostic imaging of a suspected mass may begin with mammography that includes magnification, extra compression, or extra views beyond the usual medial lateral oblique and cranial caudal views that are typically used for screening. Unlike screening mammography, diagnostic mammography may be appropriate for women of any age. In addition, sonography is invaluable for determining whether a mass is cystic or solid and is a component of most diagnostic imaging algorithms. Certain features of solid masses, such as irregular margins, internal echoes, or a width-to-height ratio <1.7 may suggest malignancy (Stavros, 1995).

BREAST IMAGING REPORTING AND DATA SYSTEM

Diagnostic imaging results should be summarized according to the Breast Imaging Reporting and Data System (BI-RADS) classification (Table 12-1) (D'Orsi, 1998). Lesions that are graded BI-RADS 5 are highly suggestive of malignancy, and ≥95 percent of these are ultimately proved to be cancerous. Decreasing numerical grades are associated with diminishing probability of malignancy.

Table 12-1 Breast Imaging Reporting and Data System (BI-RADS)		
BI-RADS Category	**Description**	**Examples**
0	Additional views or sonography required	Focal asymmetry, microcalcifications, or a mass identified on a screening mammogram
1	No abnormalities identified	Normal fat and fibroglandular tissue
2	Not entirely normal, but definitely benign	Fat necrosis from a prior excision, stable biopsy-proven fibroadenoma, stable cyst
3	Probably benign	Circumscribed mass that has been followed for <2 years
4A	Low suspicion for malignancy, but intervention required	Probable fibroadenoma, complicated cyst
4B	Intermediate suspicion for malignancy, intervention required	Partially indistinctly marginated mass otherwise consistent with a fibroadenoma
4C	Moderate suspicion, but not classic for carcinoma	New cluster of fine pleomorphic calcifications, ill-defined irregular solid mass
5	Almost certainly malignant	Spiculated mass, fine linear and branching calcifications
6	Biopsy-proven carcinoma	Biopsy-proven carcinoma

Breast Biopsy

Evaluation of a solid breast mass is completed by needle biopsy. These biopsies should be performed after an imaging test or a minimum of 2 weeks prior to an imaging test, as resulting tissue trauma can produce image artifacts that simulate malignancy (Sickles, 1983). Options include fine-needle aspiration (FNA) biopsy or core-needle biopsy (Boerner, 1999). The trend in recent years has been to prefer core-needle biopsy (Tabbara, 2000). Although FNA takes less time to perform and is less expensive than core-needle biopsy, it is less likely to provide a specific diagnosis and has a higher insufficient sample rate (Shannon, 2001). Fine-needle aspiration retrieves clusters of epithelial cells that may be interpreted as benign or malignant, but cannot reliably differentiate between benign proliferative lesions and fibroepithelial neoplasms or between ductal carcinoma in situ and invasive cancer (Boerner, 1999; Ringberg, 2001).

In contrast, core-needle biopsy is performed using an automated device that takes one core at a time, or using a vacuum-assisted device that once initially positioned, delivers multiple cores. Needle biopsy of solid masses is generally preferred prior to excision, as the results of the biopsy contribute significantly to surgical planning (Cox, 1995).

Triple Test

The combination of clinical examination, imaging, and needle biopsy is called the *triple test* . When all three assessments suggest a benign lesion or all three suggest a breast cancer, the triple test is said to be concordant. A concordant benign triple test is >99 percent accurate, and breast lumps in this category can be followed by clinical examination alone at 6-month intervals (Table 12-2). If any of the three assessments suggests malignancy, the lump should be excised regardless of results from the other two. It is always appropriate to offer excision of a fully evaluated breast lump, even after a benign concordant triple test, as breast lumps can be a source of significant anxiety.

[a] Cytologic diagnoses of "definitively malignant" and "suspicious for malignancy" are considered positive. The triple test includes clinical examination, imaging, and needle biopsy. Only cases that were malignant by all three tests, or benign by all three tests are included in the calculations.

Cysts

Most breast cysts arise from apocrine metaplasia of lobular acini. They are generally lined by a single layer of epithelium that ranges from flattened to columnar. One autopsy series that included 725 women reported microcysts in 58 percent and cysts >1 cm in 21 percent (Davies, 1964). The incidence of breast cysts peaks between 40 and 50 years, and it has been estimated that the lifetime incidence of palpable breast cysts is approximately 7 percent (Haagensen, 1986b).

Breasts cysts are diagnosed and classified by sonographic examination. There are three types of cysts: simple, complicated, and complex (Berg, 2003). Simple cysts are sonolucent, have a smooth margin, and show enhanced through-transmission (Fig. 12-5). These lesions do not require special management or monitoring, but they may be aspirated if painful. Recurrent cysts can be re-imaged and re-aspirated, but recurrent symptomatic cysts are best managed by excision.

Sonographic appearance of palpable breast masses. **A.** Simple cyst. **B.** Silicone granuloma. **C.** Fibroglandular ridge. **D.** Fibroadenoma. **E.** Complex cyst. **F.** Cancer.

Complicated cysts show internal echoes with sonography and can sometimes be indistinguishable from solid masses. Internal echoes are usually caused by proteinaceous debris, but all complicated cysts should be aspirated. The aspirated material may be submitted for culture if it is purulent, or for cytology if there are worrisome clinical or imaging features. If the sonographic abnormality does not resolve completely with aspiration, a core-needle biopsy is usually performed.

Complex cysts show septa or intracystic masses on sonographic evaluation. An intracystic mass usually represents a papilloma, but medullary carcinoma, papillary carcinoma, and some infiltrating ductal carcinomas can present as complex cysts. Although some have advocated core-needle biopsy for the evaluation of complex cysts, this procedure can decompress a cyst making it difficult to localize at the time of surgery. Additionally, papillary lesions diagnosed by needle biopsy will require excision. Thus, it seems reasonable to recommend excision of all complex cysts.

Fibroadenoma

Fibroadenomas represent a focal developmental abnormality of a breast lobule and as such are not true neoplasms. Histologically, fibroadenomas are comprised of glandular and cystic epithelial structures surrounded by a cellular stroma. Fibroadenomas account for 7 to 13 percent of breast clinic visits and had a prevalence of 9 percent in one autopsy series (Dent, 1988; Franyz, 1951). They often present in adolescence, are recognized most frequently in premenopausal women, and usually spontaneously involute at menopause.

Fibroadenomas classified as benign concordant by the triple test can be safely followed without excision. Because some fibroadenomas may grow large, and because benign phylloides tumors are often indistinguishable from fibroadenomas by imaging and needle biopsy, a fibroadenoma that is growing should be excised.

Phylloides Tumors

Histologically, phylloides tumors are similar to fibroadenomas in that epithelial-lined spaces are surrounded by cellular stroma. However, with phylloides tumors, the stromal cells are monoclonal and neoplastic. Phylloides tumors are classified as benign, intermediate, or malignant, based on the degree of stromal cell atypia, number of mitoses, tumor margin characteristics, and abundance of stromal cells (Oberman, 1965). Phylloides tumors account for less than 1 percent of breast neoplasms, and the median age at diagnosis is 40 years (Haagensen, 1986a; Reinfuss, 1996).

Malignant phylloides tumors can metastasize to distant organs, with lung being the primary site. Chest radiographs or chest computed-tomography (CT) scanning are appropriate staging tests for malignant cases. Phylloides tumors rarely metastasize to lymph nodes, thus axillary staging is not required unless there are clinically positive nodes (Chaney, 2000).

Treatment consists of wide local excision with a minimum 1-cm margin. Mastectomy may be required to achieve this margin, as the

median tumor size at presentation is 5 cm. Local recurrence rates for completely excised tumors range from 8 percent for benign lesions to 36 percent for malignant lesions (Barth, 1999).

NIPPLE DISCHARGE

Fluid can be expressed from the nipple ducts of at least 40 percent of premenopausal women, 55 percent of parous women, and 74 percent of women who have lactated within 2 years (Wrensch, 1990). The fluid generally issues from more than one duct and may range from milky white to dark green or brown. Green coloration is related to the content of cholesterol diepoxides and is not suggestive of underlying infection or malignancy (Petrakis, 1988).

Multiduct discharges that are elicited only following manual expression are considered physiologic and do not require additional evaluation. However, spontaneous discharges should be considered pathologic and merit evaluation (Fig. 12-6). Spontaneous milky nipple discharge, also called galactorrhea, may result from a variety of causes (Tables 12-3 and 12-4) (see Chap. 15, Etiology of Hyperprolactinemia). Pregnancy is another frequent cause of new-onset spontaneous discharge, and a bloody multiduct discharge during pregnancy is not uncommon.

Diagnostic algorithm to evaluate nipple discharge hCG = human chorionic gonadotropin; MRI = magnetic resonance imaging; TSH = thyroid-stimulating hormone.

Pathologic nipple discharge is defined as a spontaneous single duct discharge that is serous or bloody. The rate of underlying malignancy ranges from about 2 percent for young women with no associated findings on imaging or physical examination to 20 percent for older women with associated findings (Cabioglu, 2003; Lau, 2005). Most pathologic nipple discharges are caused by benign intraductal papillomas, which are simple milk duct polyps (Urban, 1978). They arise in the major milk ducts, generally within 2 cm of the nipple, and contain a velvety papillary epithelium on a central fibrovascular stalk.

Evaluation of a pathologic nipple discharge begins with breast examination. Careful evaluation can frequently locate a trigger point on the areolar edge that elicits the discharge when pressed. Occult blood testing and microscopic examination of the discharge can provide additional information. A glass slide that has been touched to the discharge and immediately fixed in 95-percent alcohol may be used for cytologic assessment. Nipple fluid samples are acellular in 25 percent of cases and thus cannot exclude an underlying malignancy (Papanicolaou, 1958). However, malignant cells, if found, are highly correlated with an underlying cancer (Gupta, 2004).

Following these examinations, diagnostic mammography and an assessment of the subareolar ducts by ductography, mammary ductoscopy, or sonography is indicated. Diagnostic mammography is usually negative, but may occasionally identify an underlying ductal carcinoma in situ (DCIS). Mammary ductography, also known as galactography, requires cannulating the affected duct,

injecting radiocontrast, and then performing mammography (Fig. 12-7). In contrast, ductoscopy involves dilation and cannulation of the discharging breast duct, followed by passage of an endoscope measuring only 0.6 to 1.2 mm in diameter.

An evaluation of the subareolar ducts, as described above, is required to localize an intraductal lesion for subsequent excision. However, pathologic nipple discharge is definitively diagnosed and treated by subareolar duct excision, which is also known as microductectomy (Locker, 1988). Subareolar duct excision can also be used to treat bothersome multiduct discharges not associated with prolactinoma.

BREAST INFECTIONS

Breast infections are generally divided into puerperal, which develop during pregnancy and lactation, and nonpuerperal.

Puerperal Infections

This staphylococcal infection of the breast is characterized by a warm, tender, diffuse erythema of the breast with systemic signs of infection such as fever, malaise, myalgias, and leukocytosis. It is successfully treated with oral or intravenous antibiotics, depending on the severity, but may also progress to form deep parenchymal abscesses that require surgical drainage. Sonographic examination is highly sensitive for identifying underlying abscesses if mastitis does not improve rapidly with antibiotics. Women with puerperal mastitis should continue to breast feed or breast pump during treatment to prevent milk stasis, which may contribute to infection progression (Thomsen, 1983). Cracked or excoriated nipples may provide a source of entry for bacteria and should be treated with lanolin-based lotions or ointments.

Focal mastitis may result from an infected galactocele. A tender mass will usually be palpable at the site of skin erythema. Needle aspiration of the galactocele and antibiotics are frequently all that is required, but recurrence or progression may mandate surgical drainage.

Nonpuerperal Infections

CELLULITIS

Uncomplicated cellulitis in a nonirradiated breast in a nonpuerperal setting is uncommon. Accordingly, its occurrence should prompt imaging and biopsies to exclude inflammatory breast cancer.

ABSCESS

Nonpuerperal breast abscesses are generally classified as peripheral or subareolar. Peripheral abscesses usually represent skin infections such as folliculitis or infection of epidermal inclusion cysts or Montgomery glands. These abscesses are all adequately treated by drainage and antibiotics.

In contrast, subareolar abscesses arise from keratin-plugged milk ducts directly behind the nipple. The abscess itself usually presents under the areola, and fistulous communications between multiple abscesses are common. Simple drainage is associated with a recurrence rate of 38 percent, thus effective treatment requires subareolar duct excision and complete removal of sinus tracts. In general, surgical drainage of breast abscesses should always be accompanied by biopsy of the abscess wall, as breast cancer occasionally presents as an abscess (Benson, 1989; Watt-Boolsen, 1987).

MASTALGIA

The prevalence of breast pain is 66 percent and is higher for women nearing menopause than for younger women (Euhus, 1997; Maddox, 1989). The precise etiology of mastalgia is unknown, but it is likely related to estrogen- and progesterone-mediated changes in interstitial water content, and therefore in interstitial pressure.

Mastalgia is generally classified as cyclic or noncyclic. Noncyclic mastalgia is often focal and shows no relationship to the menstrual cycle. Although focal mastalgia is frequently caused by a simple cyst, breast cancer occasionally presents as focal breast pain. Therefore, this complaint is evaluated by careful clinical examination, targeted imaging, and needle biopsy of any palpable or imaging abnormalities.

In contrast, cyclic mastalgia is usually bilateral, diffuse, and most severe during the late luteal phase of the menstrual cycle (Gateley, 1990). It remits with the onset of menstruation. Cyclic mastalgia requires no specific evaluation and is generally managed symptomatically with nonsteroidal anti-inflammatory agents (Fig. 12-8). A variety of other treatments have been proposed including bromocriptine, vitamin E, or oil of evening primrose, but outcomes are no better than placebo in the best randomized clinical trials, except for bromocriptine in the subset of women with elevated prolactin levels (Kumar, 1989; Mansel, 1990). For the most severe cases, several agent are effective when administered during the last 2 weeks of the menstrual cycle. These include: (1) danazol, 200 mg orally daily; (2) the selective estrogen receptor modifier, toremifene (Fareston, GTx, Memphis, TN), 20 mg orally daily, or (3) tamoxifen (Nolvadex, AstraZeneca, Wilmington, DE), 20 mg orally daily. Pregnancy must first be excluded and then avoided if these medications are used.

BENIGN PROLIFERATIVE BREAST DISEASE

Fibrocystic Change

The primary tissue components of the breast are fat, fibrous stroma, and epithelial structures. The hormonally responsive component is the epithelium, but considerable paracrine communication exists between the epithelium and stroma. Hormonal stimulation may result in dilated fluid-filled lobular acini interpreted as microcysts on histologic sections and is usually accompanied by relative stromal abundance. This is commonly referred to as fibrocystic change. Depending on the particular pattern of epithelial structures and associated stroma, a breast may appear mammographically dense, feel nodular to palpation, or both. Fibrocystic change is generally classified as proliferative or nonproliferative according to the epithelial features of the process.

Ductal and Lobular Hyperplasia

For the most part, proliferative changes develop in the terminal ducts and acini of the lobules. These structures are usually lined by an inner layer of cuboidal luminal epithelial cells and an outer layer of myoepithelial cells. Proliferation of the luminal epithelial cells results in terminal ducts or acini with several layers of cells, which is referred to as ductal or lobular hyperplasia, respectively. As this process progresses the terminal ducts or acini become packed with cells, which begin to show nuclear atypia. This condition is referred to as atypical ductal hyperplasia (ADH) or atypical lobular hyperplasia (ALH), respectively. As more and more terminal ducts or acini become involved, the condition is recognized as ductal carcinoma in situ (DCIS) or lobular carcinoma in situ (LCIS), depending on whether the cells are arising from the ducts or acini (Fig. 12-9) (Ringberg, 2001). In general, women with typical epithelial hyperplasia have a relative risk for breast cancer of about 1.5, whereas women with atypical hyperplasia have a relative

risk of approximately 4.5 (Dupont, 1993; Sneige, 2002).

FIGURE 12-9

Histologic progression from normal breast tissue to cancer. DCIS = ductal carcinoma in situ.

These traditional histologic designations are gradually being replaced by a standardized scoring system that reflects the risk for subsequent breast cancer. Based on cell of origin, extent, and grade, the proposed categories include ductal intraepithelial neoplasia (DIN) low risk, 1, 2, and 3, and lobular intraepithelial neoplasia (LIN) 1, 2, or 3 (Bratthauer, 2002; Tavassoli, 2005).

LOBULAR CARCINOMA IN SITU

Lobular carcinoma in situ is not associated with any specific mammographic or palpable features and thus is only diagnosed incidentally. Classic LCIS has not traditionally been viewed as a direct precursor of breast cancer, but rather as a marker of increased breast cancer risk, because subsequent breast cancers develop with nearly the same frequency in both breasts (Chuba, 2005). The risk of subsequent breast cancer is approximately 1 percent per year but is modified upward by early age at diagnosis, family history of breast cancer, and extensive disease (Bodian, 1996).

Lobular carcinoma in situ tends to be multifocal and bilateral, and therefore local excision with clear margins is frequently not possible and not necessary. Accordingly, management options include enhanced surveillance, chemoprevention, or bilateral prophylactic mastectomy. Enhanced surveillance may include twice-yearly clinical examinations and mammography alternating with screening magnetic resonance (MR) imaging. There are no data yet to show that screening MR imaging reduces breast cancer mortality among women with LCIS, but the infiltrating lobular cancers that can develop are frequently mammographically occult. Five years of tamoxifen has been shown to reduce breast cancer incidence by 56 percent in women with LCIS (Fisher, 1998). Raloxifene (Evista, Eli Lilly, Indianapolis, IN) may be an option for postmenopausal women (Vogel, 2006). Most women with LCIS do not opt for bilateral prophylactic mastectomy. However, for women with LCIS and a family history of breast cancer or for women who are continuing to require multiple biopsies, it is often a welcome solution.

DUCTAL CARCINOMA IN SITU

Ductal carcinoma in situ can be understood as a condition in which cancer cells fill portions of a mammary ductal system without invading beyond the duct's basement membrane (Ringberg, 2001). Although DCIS cells have accumulated many of the DNA changes common to invasive breast cancer, they lack certain critical changes that would permit them to persist outside of the duct (Aubele, 2002). Ductal carcinoma in situ is currently classified as stage 0 breast cancer.

The incidence of DCIS in the U.S. has increased in parallel with that of invasive breast cancer during the last two decades, but similar to invasive breast cancer, the incidence has plateaued during the last several years (Chuba, 2005). Ductal carcinoma in situ currently accounts for 25 to 30 percent of all breast cancers in the United States. It is most commonly diagnosed by screening mammography as it is frequently associated with pleomorphic, linear, or branching calcifications (Fig. 12-10).

Ductal carcinoma in situ is classified by morphologic type, the presence or absence of comedonecrosis, and nuclear grade. The common morphologic types include cribriform, solid, micropapillary, and comedo (Fig. 12-11). Comedonecrosis appears as a necrotic eosinophilic core down the center of a duct packed with cancer cells. Of all of the classifying variables, nuclear grade is the most predictive for associated invasive cancer, extent of disease, and recurrence after treatment (Ringberg, 2001).

Morphologic types of ductal carcinoma in situ (DCIS).

Incompletely treated DCIS may recur locally, and 50 percent of recurrences are associated with fully developed invasive breast cancer. The principal treatment of DCIS is wide excision with a negative margin. This may require mastectomy if DCIS is extensive or if there are other contraindications to breast conservation. When breast conservation is possible, postoperative breast irradiation will reduce the local recurrence rate from 18 percent to 9 percent and is considered standard adjuvant treatment (Fisher, 1993).

For those treated with breast conservation and radiation, breast cancerâ€"specific survival is 96 percent (Fig. 12-12) (Solin, 1996).

FIGURE 12-12

Cause-specific and overall survival for ductal carcinoma in situ. *(From Solin, 1996, with permission.)*

Axillary staging is generally not included in the management of DCIS, although some have advocated sentinel node biopsy for large, high-grade DCIS diagnosed by needle biopsy and treated by lumpectomy, as occult invasive cancer is diagnosed in 10 percent (Wilkie, 2005). Sentinel lymph node (SLN) biopsy in conjunction with mastectomy is less controversial, as it is not possible to go back and perform SLN biopsy if an occult invasive cancer is diagnosed in this setting.

Five years of tamoxifen is recommended for estrogen receptorâ€"positive DCIS treated by breast conservation (Fisher, 1999). Although tamoxifen is not associated with a statistically significant improvement in overall survival, it does significantly reduce the incidence of ipsilateral invasive cancer and also reduces the risk of contralateral breast cancer.

Paget Disease of the Nipple

This type of DCIS presents as a focal eczematous rash of the nipple (Fig. 12-13). Ductal carcinoma cells, responding to chemoattractants secreted by cells in the dermis, migrate to the surface of the nipple inducing skin breakdown (Schelfhout, 2000). The condition is easily diagnosed histologically following excision of the affected nipple tip after nipple-areolar blockade using local anesthetic. Evaluation should also include careful clinical examination, as an associated mass is identified in about 60 percent of cases (Ashikari, 1970). Among those with no palpable abnormalities, mammography will show suspicious densities or calcifications in 21 percent (Ikeda, 1993). An underlying DCIS is identified in about two thirds of cases and an invasive cancer in approximately one third (Ashikari, 1970).

Treatment includes wide excision with negative margins. Breast conservation, which requires central breast resection including the nipple-areolar complex and all identifiable underlying disease, is followed by postoperative breast irradiation (Bijker, 2001). Axillary staging by sentinel node biopsy is not required unless an invasive component is identified or total mastectomy is performed.

BREAST CANCER RISK FACTORS

The most profound breast cancer risk factor is female gender. In addition, the incidence of breast cancer, as for most other cancers, increases with advancing age. Other significant risk factors are related to reproductive variables, benign proliferative breast disease, and family history of breast or ovarian cancer.

Reproductive Factors

OVULATORY CYCLES

Ovulatory menstrual cycles exert stress on the breast epithelium by inducing proliferation in the late luteal phase. If conception does not occur, proliferation is followed by programmed cell death (Anderson, 1982; Soderqvist, 1997). Early age at menarche is associated with earlier onset of ovulatory cycles and increased breast cancer risk (den Tonkelaar, 1996; Vihko, 1986). Conversely, early menopause, whether it is natural or surgical, is associated with a reduced breast cancer risk (Kvale, 1988). Indeed, the lifetime number of ovulatory cycles is linearly related to breast cancer risk (Clavel-Chapelon, 2002). Pregnancy generates very high levels of circulating estradiol which is associated with a transient increase in short-term risk. But pregnancy also provides relief from ovarian cycling. Consequently, increasing parity is associated with reduced lifetime risk.

PREGNANCY

The breast is unique among all human organs in that it exists as a primordium for a decade or more before entering a highly proliferative state at menarche, and then does not fully mature until the first live birth. Immature breast epithelium is more susceptible to carcinogens than postlactational epithelium (Russo, 1996). Therefore, the longer a first live birth is delayed, the greater the breast cancer risk. Relative to nulliparity, first live births before the age of 28 years are associated with reduced breast cancer risk, whereas those thereafter are associated with increased risk (Gail, 1989). Both early age at first live birth and greater numbers of live births are associated with reduced breast cancer risk (Layde, 1989; MacMahon, 1970; Pathak, 1986; Pike, 1983).

Benign Proliferative Breast Disease and Family History

As discussed above, benign proliferative breast disease is a marker of breast cancer risk, with relative risks ranging from 1.5 to 4.5 depending on whether epithelial cells are atypical or not (Dupont, 1993). A family history of breast cancer may also indicate an increased breast cancer risk, particularly with affected first-degree relatives (parents, siblings, or offspring), an early age at diagnosis, or bilateral breast cancer (Claus, 1994; Colditz, 1993).

Other Factors

Increased mammographic density is emerging as an important breast cancer risk factor. The incidence of breast cancer among women with almost entirely dense breasts is three- to sixfold greater than that of women with almost entirely fatty breasts, a relative risk approaching that conferred by a diagnosis of atypical ductal hyperplasia (Fig. 12-14) (Barlow, 2006; Boyd, 1995; Byrne, 1995; Ursin, 2003). Other minor breast cancer risk factors include alcohol consumption (>2 ounces per day), increased body mass index (for postmenopausal women only), increased height, and current use of combined estrogen-progestin hormone replacement therapy (Friedenreich, 2001; Lahmann, 2004; Macinnis, 2004; Smith-Warner, 1998; Writing Group for the Women's Health Initiative Investigators, 2002). Use of estrogen-only hormone replacement therapy has not been convincingly associated with an increased breast cancer risk (The Women's Health Initiative Steering Committee, 2004). In general, all of these risk factors are more prevalent in developed countries than less developed countries, Consequently, breast cancer is more common in industrialized cultures (Parkin, 2001).

Relative risk of breast cancer increases with increasing mammographic breast density. *(From Santen, 2005, with permission.)*

Gail Model

In 1989, Gail evaluated more than a dozen potential breast cancer risk factors in a population of women undergoing screening mammography (Gail, 1989). Of these, age, age at menarche, age at first live birth, number of breast biopsies, and number of first-degree relatives with breast cancer emerged as the most important factors. The Gail model is a mathematical tool for calculating breast cancer risk based on these risk factors and has been independently validated (Costantino, 1999; Rockhill, 2001). A risk calculator is available to physicians through the National Cancer Institute website at http://www.cancer.gov/bcrisktool/ . However, shortcomings of the model include an inability to predict which women in a large group will actually develop breast cancer, failure to account for other risk factors (such as LCIS), and failure to adequately address family history factors. Although newer models, such as the Tyrer-Cuzick model, combine genetic risk factors with the established Gail factors and also include parity, age at menopause, history of LCIS or atypical ductal hyperplasia, height, and body mass index, but no other model has been independently validated as extensively as the Gail model (Tyrer, 2004). A recent modification of the Gail model includes a factor for mammographic density (Chen, 2006).

Breast Cancer Genetics

Nearly 30 percent of breast cancers have some familial component, but fewer than 10 percent are caused by inherited mutations in major breast cancer susceptibility genes (Antoniou, 2006; Lichtenstein, 2000). These genes operate in an autosomal dominant fashion and are involved in DNA repair or in controlling the cell cycle so that DNA can be repaired before the cell divides.

Family histories that suggest inherited susceptibility include early-onset breast cancer (<50 years), bilateral breast cancer, male breast cancer, multiple affected relatives in one generation, breast cancer in multiple generations, development of cancers that are known to be associated with a particular syndrome, and two or more cancers in one relative, especially if they develop at an early age. CancerGene is a widely used computer program for estimating gene mutation probabilities based on family history information (http://www4.utsouthwestern.edu/breasthealth/cagene). When possible, genetic testing is a powerful tool for determining who in the family is truly at high risk.

INHERITED BREAST-OVARIAN CANCER SYNDROME

This syndrome accounts for 5 to 7 percent of breast cancers (Malone, 2000). About 45 percent of individuals with this syndrome carry a *BRCA1* gene mutation and 35 percent a *BRCA2* mutation. Twenty percent of families with inherited breast-ovarian cancer syndrome test negative for *BRCA1* and *BRCA2* gene mutations, suggesting that other genes remain to be identified. Hallmarks of the BRCA1 form include early age at breast cancer diagnosis (median 44 years); high-grade, estrogen and progesterone receptorâ€"negative breast cancers; and associated ovarian cancer (Foulkes, 2004). The lifetime risk for breast cancer ranges from 35 to 80 percent, and for ovarian cancer 16 to 57 percent (Easton, 1995; Ford, 1994, 1998). Individuals who have developed both breast and ovarian cancer have an 86-percent probability of carrying a BRCA gene mutation (Cvelbar, 2005).

Women with *BRCA2* gene mutations develop breast cancer at about the same age as women with sporadic breast cancer, thus age at diagnosis is not usually a good criterion for recognizing this syndrome. Ovarian cancer is an associated cancer, but develops less frequently than it does in BRCA1 families. Males with *BRCA2* mutations develop breast cancer at about the same frequency as females without mutations, and 4 to 40 percent of male breast cancers are related to *BRCA2* mutations (Friedman, 1997; Thorlacius, 1996). Other associated cancers are listed in Table 12-5. Early premenopausal bilateral oophorectomy significantly reduces the incidence of both breast and ovarian cancer in women with inherited breast-ovarian cancer syndrome (Kauf, 2002; Rebbeck, 2002).

Table 12-5 Genetic Syndromes Associated with an Increased Risk of Breast Cancer

Syndrome Name	Genetic Mutation	Associated Disorders
Inherited breast-ovarian cancer	BRCA1, BRCA2	Cancers of the breast, ovary, pancreas, stomach, biliary system, and prostate and melanoma; male breast cancer for BRCA2
Li-Fraumeni	p53	Sarcoma, leukemia, melanoma and cancers of the breast, brain, adrenal cortex, pancreas, lung, cervix, and prostate
Cowden	PTEN	Breast: adenosis, fibrosis, hamartoma, fibroadenoma, and cancer (male and female); thyroid disease; ileum and colon hamartomatous polyps; facial tricholemmomas; macrocephaly; and oral papillomatosis
Peutz-Jegher	LKB1	Gastrointestinal hamartomatous polyps; cancers of the breast, small bowel, colon/rectum, pancreas, ovary, endometrium, cervix, lung, and testicle; and oral melanin pigmentation
$p16^{INK4a}$ and $p14^{ARF}$	$p16^{INK4a}$, $p14^{ARF}$	Leukemia/lymphoma, melanoma and cancers of the breast, pancreas, cervix, gallbladder, lung, larynx, prostate, liver, and intestine
Ataxia telangiectasia mutated	ATM	Lymphoma, leukemia, and breast cancer; cerebellar ataxia; telangiectasias; vitiligo; and cafÃ©-au-lait spots

CHK2	CHK2	Sarcoma, leukemia, melanoma and cancers of the brain, adrenal cortex, pancreas, lung, cervix, and prostate; male and female breast cancer

p16^{INK4a} and p14^{ARF} may also be known as dysplastic nevus syndromes.

Other recognized gene syndromes are associated with increased breast cancer risk (see Table 12-5). Their associated mutations affect genes involved with DNA repair, growth factor signaling, and cell-cell interactions. It is increasingly recognized that mutations in these genes, although rare, can cause predisposition syndromes that are very similar to those caused by *BRCA1* and *BRCA2* mutations.

Treatment options for breast cancers that arise in the context of an inherited predisposition syndrome are the same as for sporadic breast cancers. However, many of these women choose bilateral mastectomy, as the risk of an ipsilateral second primary breast cancer in a preserved breast can be as high as 3 to 4 percent annually, and the risk of a contralateral breast cancer is similar (Haffty, 2002; Seynaevea, 2004). Breast conservation is, however, an acceptable option for a highly motivated and well-informed patient (Robson, 1999).

BREAST CANCER SCREENING

Screening Mammography

This radiographic test is currently the best available and most thoroughly validated breast cancer screening test available. It has been evaluated in eight large randomized trials, the most recent of which was conducted in Canada in the 1980s (Begg, 2002). Controversies surrounding the benefits of screening mammography largely center on the impact of the test on breast cancerâ€"specific and overall mortality. However, at this time, it is generally accepted that for women aged 50 to 69 years, screening mammography reduces breast cancer mortality. Considerable uncertainty remains for women between the ages of 40 and 49, but several influential organizations including the American Cancer Society, the American Medical Association, and the American College of Radiology have recommended that yearly screening mammography begin at age 40. Recent improvements in screening mammography including digital mammography and computer-assisted diagnosis have improved the sensitivity of the test for some subgroups, challenging the contemporary relevance of older screening trials (Pisano, 2005).

It is important to recognize that most women with screen-detected abnormalities (~95 percent) do not have breast cancer, although the true-positive rate increases with increasing age (Feig, 2000). In addition, up to 25 percent of women diagnosed with breast cancer will have had a normal mammogram in the preceding 12 to 24 months.

Screening Sonography

This modality identifies mammographically occult breast cancer in less than 1 percent of women, but in one large study this translated into a 42-percent increase in screen-detected cancers (Gordon, 2002; Kolb, 2002). Screening sonography, however, is time consuming to perform and the accuracy is highly dependent on the operator.

Screening Magnetic Resonance Imaging

This screening option has recently been evaluated among genetically high-risk women. It is particularly attractive in this group of women, who develop breast cancer at a rate of 2 percent per year between the ages of 25 and 50, a time during which mammography sensitivity is reduced by dense breast tissue. In general, MR imaging shows higher sensitivity and specificity than mammography, but the test has been criticized for its expense and high false-positive rate (Leach, 2005; Stoutjesdijk, 2001; Tilanus-Linthorst, 2000; Warner, 2001). Nevertheless, for 100 women with a strong family history of breast cancer and a negative mammogram, nine abnormal MR imaging scans would be expected, and three of these would represent mammographically occult breast cancer.

Breast MR imaging requires specially trained radiologists, specialized equipment (a breast coil and a high-resolution magnet), and

is performed with and without intravenous gadolinium contrast (Orel, 2001). Areas of suspicious enhancement identified by MR imaging are evaluated by targeted sonographic examination and biopsied under sonographic guidance. If a lesion is not visible during sonography, then MR imagingâ€“guided core biopsy is performed.

Other Radiologic Tools

Other screening modalities in the developmental stage include breast tomosynthesis, sestamibi scanning, electrical impedance scanning, and thermography (Dobbins, 2003; Martin, 2002; Parisky, 2003; Sampalis, 2002). Of these, breast tomosynthesis warrants special mention, as it is likely to be adopted into the clinic in the near future. Tomosynthesis is a digital approach that obtains multiple images as the x-ray source and collector are rotated around the breast. Image slices are then reconstructed by a computer. This approach enhances calcifications and densities that would normally be obscured by intervening dense tissue.

Screening Physical Examination

The value of a screening clinical breast examination (CBE) performed by health care providers should not be neglected (Jatoi, 2003). Four of the large randomized mammography trials collected information on CBE and found that 44 to 74 percent of the breast cancers were detected by this approach. Sensitivity and specificity were higher for CBE than mammography among young women.

Enthusiasm for breast self-examination (BSE) has diminished subsequent to publication of a very large randomized trial performed in Shanghai, China that found no improvement in mortality (Thomas, 2002). Although there is less interest in promoting systematic breast self-examination, it seems reasonable to encourage women to remain breast-aware.

INVASIVE BREAST CANCER

In the U.S., breast cancer is the most common cancer in women and the second most common cause of cancer-related mortality (second to lung) (Chuba, 2005). Although the incidence of breast cancer increased steadily in the U.S. through the 1980s and 1990s, it has leveled at about 125 cases per year per 100,000 and is declining for some ethnicities (Fig. 12-15).

Tumor Characteristics

Primary cancers of the breast comprise 97 percent of malignancies affecting the breast, whereas 3 percent represent metastases from other sites. The most common of these, in descending order, are the contralateral breast, lymphoma, lung, and melanoma (Georgiannos, 2001). Cancers of mammary epithelial structures account for the vast majority of primary breast cancer. Infiltrating ductal carcinoma is the most common form of invasive breast cancer (~80 percent), and infiltrating lobular carcinoma is the second most common (~15 percent). Other malignancies such as phylloides tumors, sarcoma, and lymphoma comprise the remainder.

Apart from stage, the primary tumor characteristics that most influence prognosis and treatment decisions are hormone receptor status, nuclear grade, and Her-2/neu expression (Bast, 2001). Approximately two thirds of breast cancers are estrogen and progesterone receptor positive. This feature is generally associated with a better prognosis and more treatment options.

Her-2/neu is a membrane tyrosine kinase that cooperates with other Her-family receptors to generate proliferation and survival signals in breast cancer cells. Approximately 25 percent of breast cancers have increased expression of Her-2/neu (Masood, 2005). These cancers are usually sensitive to the humanized monoclonal antibody, trastuzumab (Herceptin, Genentech, South San Francisco, CA), which represents the first in a new class of targeted therapies (Plosker, 2006).

Recently, gene expression profiling has been used to classify individual tumors, and it is anticipated that in the future, individualized therapies will be selected based on the pattern of nuclear and growth factor receptors that are active in a given tumor (Habel, 2006; van de Vijver, 2002).

Breast Cancer Staging

Careful breast cancer staging is essential for predicting outcome, planning treatment, and comparing treatment effects in clinical trials. Each patient is assigned both a clinical and a pathologic stage. The clinical stage is based on clinical examination and radiographic findings, whereas a pathologic stage is based on actual tumor measurements and pathologic assessments of lymph nodes after primary surgery. Surgical staging of breast cancer is based on the TNM system, which includes primary tumor size (T), regional lymph node involvement (N), and presence of distant metastases (M) (Table 12-6). For patients with a clinically and sonographically negative axilla, sentinel lymph node biopsy has largely replaced complete axillary dissection for nodal staging (Giuliano, 1995; Lyman, 2005). Alternatively, axillary metastases may be diagnosed preoperatively by sonography-guided needle biopsy in 18 percent of patients with clinically negative axillae (Sapino, 2003).

The most common metastatic site in breast cancer is the bone, and practice varies with respect to screening for metastatic disease. However, common screening modalities include CT of the chest, abdomen, and pelvis combined with bone scintigraphy or combined whole body positron emission tomography and CT (PET/CT) (Kumar, 2005). Bone scintigraphy is usually recommended in patients assessed by PET/CT, as PET/CT can miss osteolytic bone metastases.

Breast Cancer Treatment

Breast cancer is best treated in a multidisciplinary environment that includes surgeons, medical oncologists, and radiation oncologists. Surgery and radiation therapy are aimed at eliminating all local or regional tumor in a way that maximizes cosmetics and minimizes the risk of local or regional recurrence. There is some evidence that these local modalities reduce the risk of subsequent metastases and therefore impact survival (Early Breast Cancer Trialists Collaborative Group, 2005). However, a significant proportion of patients with apparently localized disease have tumor cells detectable in their blood or bone marrow at diagnosis, making systemic treatment with chemotherapy, hormone manipulation, or targeted therapies the primary approach for reducing the risk of metastases and death (Euhus, 2007).

SURGERY

Although Halstead revolutionized the treatment of breast cancer by demonstrating improved outcome for patients treated with radical mastectomy, results from recent randomized clinical trials have appropriately fostered a trend towards less aggressive surgery (Halstead, 1894). Specifically, it has been thoroughly documented that lumpectomy with postoperative radiation therapy results in the same breast cancerâ€"specific survival as total mastectomy (Fisher, 2002a, 2002b). During surgery, more extensive axillary lymph node dissection is indicated for patients with a positive sentinel node or with axillary disease diagnosed by needle biopsy (Lyman, 2005). The procedure results in lymphedema in 15 to 50 percent of women, depending on how it is measured (Morrell, 2005). It is also associated with persistent shoulder or arm symptoms in up to 70 percent (Kuehn, 2000). Following lumpectomy, whole breast irradiation is the standard, although preliminary data for accelerated partial breast irradiation are encouraging (Jeruss, 2006; Zannis, 2005).

CHEMOTHERAPY

In the past, adjuvant chemotherapy was reserved for patients with nodal metastases and was always given after definitive surgery. However, randomized prospective trials have shown that adjuvant chemotherapy improves survival for high-risk node-negative patients as well (Fisher, 2004; National Institutes of Health, 2000). More and more, however, the decision for chemotherapy is influenced by specific measures of tumor biology.

If used, adjuvant chemotherapy is usually administered after primary surgery but before radiation therapy. Neoadjuvant chemotherapy is given prior to definitive surgery and is gaining popularity. Neoadjuvant chemotherapy permits assessment of the sensitivity of a given tumor to the selected agents, and the tumor shrinkage that often results permits less aggressive surgery.

Modern breast cancer chemotherapy usually includes an anthracycline such as doxorubicin (Adriamycin), in conjunction with cyclophosphamide (Trudeau, 2005). Taxanes may replace anthracyclines in the near future, as they are less toxic and are

associated with equivalent or superior outcomes (Nabholtz, 2005). Chemotherapeutic agents are described more fully in Chapter 27.

HORMONAL THERAPY AND TARGETED THERAPIES

Adjuvant hormonal therapy is used for estrogen receptorâ€“positive tumors. Options include the selective estrogen receptor modifier, tamoxifen, in pre- or postmenopausal women or an aromatase inhibitor in postmenopausal women (Jaiyesimi, 1995; Kudachadkar, 2005). In postmenopausal women, most circulating estradiol is derived from the peripheral conversion of androgens by the enzyme aromatase. Administration of aromatase inhibitors reduces circulating estradiol to nearly undetectable levels in postmenopausal women. The addition of an aromatase inhibitor after tamoxifen is associated with a 23 to 39 percent improvement in disease-free survival and a nearly 50-percent reduction in contralateral breast cancer (Geisler, 2006).

Therapies that target specific biological pathways are becoming available. Trastuzumab is a humanized monoclonal antibody that is very effective against Her-2/neu overexpressing tumors, and bevacizumab (Avastin, Genentech, South San Francisco, CA), a vascular endothelial growth factor (VEGF) antagonist, is finding a place in the clinic (Gonzalez-Angulo, 2006; Rugo, 2004). In addition, dozens of other antibodies and small molecules that target growth factors and receptor tyrosine kinases or their intermediaries are currently being evaluated in clinical trials (Kaklamani, 2004).

SURVEILLANCE

Long-term surveillance of breast cancer patients after treatment includes periodic history and physical examination, both general and directed at eliciting signs or symptoms of recurrence. Women who elected breast conservation should be aware that the remaining breast tissue requires surveillance indefinitely, as ipsilateral second primary breast cancers develop at a rate of approximately 1 percent per year and contralateral breast cancers at approximately 0.7 percent per year (Fatouros, 2005; Fisher, 1984; Gao, 2003). Laboratory and imaging tests are obtained to further evaluate specific signs or symptoms. The use of screening tests other than mammography to identify asymptomatic recurrences is not recommended (Emens, 2003; Khatcheressian, 2006).

Inflammatory Breast Cancer

Inflammatory breast cancer accounts for about 6 percent of breast cancers, but its incidence is increasing (Chang, 1998). This cancer presents with skin changes that can range from a faint red blush to a flaming red rash associated with skin edema (peau d'orange change) (Fig. 12-16). It is distinguished from a neglected advanced primary breast cancer by its rapid onset and progression within just a few weeks. The cancer spreads rapidly throughout the entire breast and creates diffuse induration. As a result, the breast may enlarge to two to three times its original volume within weeks (Taylor, 1938).

Although mastitis or even congestive heart failure can produce a similar clinical appearance, inflammatory breast cancer must be definitively excluded. This always includes diagnostic mammography and punch biopsy of the skin, but may require multiple biopsies and additional imaging tests such as MR imaging or sestamibi scanning. Treatment begins with induction chemotherapy, which is followed by modified radical mastectomy (total mastectomy and axillary dissection) and then postoperative chest wall irradiation with or without additional chemotherapy (Cariati, 2005). Five-year survival is 30 to 55 percent, which is significantly worse than for neglected advanced primary breast cancer (Brenner, 2002; Harris, 2003).

BREAST CANCER PREVENTION

Obesity and a sedentary life style are two modifiable risk factors that should be addressed in high- and lower-risk women. Although some studies have reported a reduced breast cancer risk among women consuming five or more servings a day of fresh fruits and vegetables, prospective studies have not convincingly linked any single dietary practice to breast cancer incidence (Gandini, 2000; Meskens, 2005). Regular physical activity is consistently associated with reduced breast cancer risk in clinical trials (Lee, 2003).

Women at high risk for breast cancer have three main options: (1) enhanced surveillance, (2) chemoprevention, or (3) prophylactic surgery. Enhanced surveillance usually consists of clinical examination every 6 months, alternating mammography with breast MR imaging or screening sonography. Enhanced surveillance can begin 10 years before the earliest age of breast cancer diagnosis in a family.

The U.S. Food and Drug Administration has approved tamoxifen for breast cancer chemoprevention in pre- or postmenopausal women 35 years or older with a 5-year Gail model risk ≥1.7 percent. Five years of tamoxifen is associated with a 49-percent reduction in breast cancer incidence, including both invasive breast cancer and DCIS (Fisher, 1998). However, tamoxifen is associated with an increased incidence of endometrial cancer and an increased risk of thromboembolic disease including deep vein thrombosis, pulmonary embolism, and stroke. Raloxifene is another selective estrogen receptor modulator that reduces the incidence of invasive breast cancer to the same extent as tamoxifen, but it does not reduce the risk of DCIS to the same extent (Vogel, 2006). Raloxifene has been associated with a lower risk of endometrial cancer and thromboembolic complications than tamoxifen. Raloxifene has not been evaluated in premenopausal women, although tamoxifen has.

Prophylactic surgery is usually reserved for women at very high risk for breast cancer. This includes women with inherited mutations in breast cancer predisposition genes and some women with LCIS, particularly if it is extensive or associated with a family history of breast cancer. Bilateral prophylactic oophorectomy performed in premenopausal women with BRCA gene mutations has been shown to reduce the risk of breast cancer by 50 percent and the risk of ovarian cancer by more than 90 percent (Eisen, 2005; Kauf, 2002; Rebbeck, 2002). Bilateral prophylactic mastectomy is usually performed as a skin-sparing procedure with immediate reconstruction. Bilateral prophylactic mastectomy reduces breast cancer risk by more than 90 percent, but it is currently unclear whether overall or breast cancerâ€"specific survival is increased (Hartmann, 2001; Lostumbo, 2004; McDonnell, 2001; Peralta, 2000). Breast cancers may develop after prophylactic mastectomy if there is residual breast tissue (usually in the upper outer quadrant or axillary tail). They may also develop in the skin of a mastectomy flap.

PSYCHOSOCIAL ISSUES AND FEMALE SEXUALITY: INTRODUCTION

Thirty years ago, an article in *Science* written by psychiatrist George Engel coined a word to describe a developing paradigm for patient care, the "biopsychosocial model" (Engel, 1977). The model encouraged formulating treatments that considered the mind and body of a patient as two intertwining systems influenced by yet a third systemâ€"society (Fig. 13-1). This was perhaps the first time a distinction was drawn between "disease" and "illness", the former referring to a pathologic process and the latter to the patient's experience of that process.

Biopsychosocial model. *(Redrawn from Engel, 1977, with permission.)*

Since the introduction of the biopsychosocial model, psychological factors have been found to play a dual role in their relationship with women's reproductive health. At times psychological factors are a consequence (infertility has been linked with psychological distress), and at other times are an insidious cause of a health problem (increased hysterectomies have been found in women with a low tolerance for the physical discomfort of menstruation) (O'Hara, 1995).

Twenty years before Engel introduced his paradigm for treatment, a German developmental psychologist, Erik Erikson (1963), created a model that describes psychological maturation across the life span. Combining these two models yields a dimensional perspective helpful for the evaluation, diagnosis, and treatment of any patient, and of particular relevance in a discussion of women's mental health (Table 13-1).

Table 13-1 Biopsychosocial Development

Not only do women use more health care services in general than men in the United States, but more women approach their physicians with psychiatric complaints, and more women have comorbid illness than men (Andrade, 2003; Burt, 2005; Kessler, 1994). Coupled with the almost universal recognition that primary care is where most patients with psychiatric illness are first seen, it is likely that obstetricians and gynecologists will often be the first to evaluate a woman in psychiatric distress (Goldberg, 2003). A clinical interview such as the one presented in Table 13-2 can guide assessment of a woman and includes all three domains from the biopsychosocial model.

Table 13-2 Psychiatric Assessment of Women: Clinically Significant Considerations	
Component	**Consideration**
History of present illness and past psychiatric history	Characterize symptoms in relation to: 1. A specific phase of the menstrual cycle 2. Use of hormonal contraception 3. Pregnancy 4. The postpartum period 5. Breast feeding or weaning 6. Abortion 7. Infertility treatment 8. Hysterectomy 9. Menopausal transition
Medications	Include exogenous hormones and all over-the-counter medications and supplements
Dietary assessment	Exclude ritualistic or restrictive eating patterns, binging, self-induced vomiting, and use of diet pills, laxatives, emetics, and diuretics
Alcohol and drug use	Exclude covert use, especially of prescription medications
Family psychiatric history	Include history of premenstrual dysphoric disorders and postpartum mood disorders
Medical history	Exclude autoimmune illnesses (e.g., lupus, thyroiditis, or fibromyalgia) that may present with psychiatric symptoms
	Exclude history of sexually transmitted disease that may affect current sexual functioning and childbearing capacity
Menstrual history	Exclude pregnancy, menstruation-related symptoms (e.g., bloating, weight gain, cramping, or breast tenderness)
	Exclude perimenopausal symptoms (e.g., irregular menstrual periods or hot flushes)
Social and developmental history	Note sexual preference, relationship styles, level of satisfaction with current relationships
	Document tendency to take on certain role relationships (e.g., caregiver, nurturer, or dependent or helpless role)
	Note current or past sexual, physical, or emotional abuse
Socioeconomic status	Note level of economic support and ability to meet ongoing financial needs
	If patient is a single mother, inquire about child support.

COMMON PSYCHIATRIC PRESENTATIONS

Mood, anxiety, and alcohol or substance use disorders are three families of psychiatric disorders commonly seen and often comorbid with reproductive disorders (American Psychiatric Association, 2000a). These three groups are defined by specific criteria described by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR), published by the American Psychiatric Association in 2000. Each family is characterized by a predominant feature, and each disorder within that family is identified by specific symptoms of that feature.

Mood Disorders

The spectrum of mood disorders is divided into depressive disorders (major depressive disorder, dysthymic disorder, and depressive disorder not otherwise specified); the bipolar disorders (bipolar I, bipolar II, cyclothymic disorder, and bipolar disorder not otherwise specified); and two etiologic disorders (mood disorder due to a general medical condition and substance-induced mood disorder) (Tables 13-3 and 13-4).

Table 13-3 Diagnostic Criteria for a Major Depressive Episode
A. ≥ 5 criteria present during the same 2-week period or a change from previous functioning At least one of these: Depressed mood most of the day, nearly every day (can be irritable in kids) Markedly diminished interest or pleasure in most activities, most of the day, most days
The balance of 5 from these: Significant weight loss/gain, change in appetite, or failure to make expected gains Insomnia or hypersomnia nearly every day Psychomotor agitation or retardation nearly every day, *observable by others* Fatigue or loss of energy nearly every day Feelings of worthlessness or excessive or inappropriate guilt nearly every day Diminished ability to think or concentrate or indecisiveness Recurrent thoughts of death, recurrent suicidal ideation, plans, or attempt
B. The symptoms do not meet the criteria for a Mixed Episode
C. Symptoms cause significant distress or impairment in functioning
D. Symptoms are not due to a substance or a general medical condition
E. Symptoms not better accounted for by bereavement ≥2 months or marked
Specifiers: Mild, Moderate, or Severe with or without Psychotic Features Chronic With Catatonic Features With Melancholic Features With Atypical Features With Postpartum Onset

Table 13-4 Diagnostic Criteria for Manic Episodes
Criteria for manic episodes
A. Distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week
B. During the period of mood disturbance, ≥3 of the following symptoms have persisted to a significant degree: Inflated self-esteem or grandiosity Decreased need for sleep More talkative than usual Flight of ideas or experiences racing thoughts Distractibility Increase in activity or psychomotor agitation Excessive involvement in pleasurable or risky activities with high potential for negative or painful consequences (e.g., promiscuity or unrestrained spending)
C. The criteria for a Major Depressive Episode are not fulfilled
D. The patient is markedly impaired occupationally or socially, is psychotic, or needs to be hospitalized to prevent harm to self or others
E. The symptoms are not due to the direct physiologic effects of a substance or a general medical condition
Criteria for a hypomanic episode
A. A distinct period of persistently elevated, expansive, or irritable mood, lasting throughout at least 4 days, that is clearly abnormal from the usual mood
B. During the period of mood disturbance, ≥ 3 of the above symptoms (same as for mania) have persisted to a significant degree
C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the person when not symptomatic
D. The disturbance in mood and the change in functioning are observable by others
E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization, and there are no psychotic features
F. The symptoms are not due to the direct physiologic effects of a substance or a general medical condition

MOOD DISORDER PREVALENCE

The lifetime prevalence for mood disorders in the general U.S. population is approximately 20 percent (Kessler, 2005). Depression is the second leading cause for disability in women, and females are l.5 times more likely to suffer from a major depressive episode than men (National Institute of Mental Health, 2006). Women also commonly have one or more comorbid psychiatric disorders, most often anxiety disorder and/or substance use disorder.

DIAGNOSIS OF MOOD DISORDERS

Self-report questionnaires are often used to gauge the severity of depressive symptoms or identify individuals who require psychiatric evaluation. The Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR) is one such tool that is easily implemented for clinical use (Tables 13-5 and 13-6) (Rush, 2003). By patient report, this questionnaire assesses symptom severity required by DSM-IV-TR criteria to diagnosis major depressive disorder. Further information about the instrument is available at www.ids-qids.org .

CHECK THE ONE RESPONSE TO EACH ITEM THAT BEST DESCRIBES YOU FOR THE PAST SEVEN DAYS.

During the past seven days...

1. Falling Asleep:
- ☐ 0 I never take longer than 30 minutes to fall asleep.
- ☐ 1 I take at least 30 minutes to fall asleep, less than half the time.
- ☐ 2 I take at least 30 minutes to fall asleep, more than half the time.
- ☐ 3 I take more than 60 minutes to fall asleep, more than half the time.

2. Sleep During the Night
- ☐ 0 I do not wake up at night.
- ☐ 1 I have a restless, light sleep with a few brief awakenings each night.
- ☐ 2 I wake up at least once a night, but I go back to sleep easily.
- ☐ 3 I awaken more than once a night and stay awake for 20 minutes or more, more than half the time.

3. Waking Up Too Early:
- ☐ 0 Most of the time, I awaken no more than 30 minutes before I need to get up.
- ☐ 1 More than half the time, I awaken more than 30 minutes before I need to get up.
- ☐ 2 I almost always awaken at least one hour or so before I need to, but I go back to sleep eventually.
- ☐ 3 I awaken at least one hour before I need to, and can't go back to sleep.

4. Sleeping Too Much:
- ☐ 0 I sleep no longer than 7–8 hours/night, without napping during the day.
- ☐ 1 I sleep no longer than 10 hours in a 24-hour period including naps.
- ☐ 2 I sleep no longer than 12 hours in a 24-hour period including naps.
- ☐ 3 I sleep longer than 12 hours in a 24-hour period including naps.

During the past seven days...

5. Feeling Sad:
- ☐ 0 I do not feel sad.
- ☐ 1 I feel sad less than half the time.
- ☐ 2 I feel sad more than half the time.
- ☐ 3 I feel sad nearly all of the time.

Please complete either 6 or 7 (not both)

6. Decreased Appetite:
- ☐ 0 There is no change in my usual appetite.
- ☐ 1 I eat somewhat less often or lesser amounts of food than usual.
- ☐ 2 I eat much less than usual and only with personal effort.
- ☐ 3 I rarely eat within a 24-hour period, and only with extreme personal effort or when others persuade me to eat.

-OR-

7. Increased Appetite:
- ☐ 0 There is no change from my usual appetite.
- ☐ 1 I feel a need to eat more frequently than usual.
- ☐ 2 I regularly eat more often and/or greater amounts of food than usual.
- ☐ 3 I feel driven to overeat both at mealtime and between meals.

Please complete either 8 or 9 (not both)

8. Decreased Weight (Within the Last Two Weeks):
- ☐ 0 I have not had a change in my weight.
- ☐ 1 I feel as if I have had a slight weight loss.
- ☐ 2 I have lost 2 pounds or more.
- ☐ 3 I have lost 5 pounds or more.

-OR-

9. Increased Weight (Within the Last Two Weeks):
- ☐ 0 I have not had a change in my weight.
- ☐ 1 I feel as if I have had a slight weight gain.
- ☐ 2 I have gained 2 pounds or more.
- ☐ 3 I have gained 5 pounds or more.

During the past seven days...

10. Concentration / Decision Making:
- ☐ 0 There is no change in my usual capacity to concentrate or make decisions
- ☐ 1 I occasionally feel indecisive or find that my attention wanders.
- ☐ 2 Most of the time, I struggle to focus my attention or to make decisions
- ☐ 3 I cannot concentrate well enough to read or cannot make even minor decisions

11. View of Myself:
- ☐ 0 I see myself as equally worthwhile and deserving as other people
- ☐ 1 I am more self-blaming than usual.
- ☐ 2 I largely believe that I cause problems for others.
- ☐ 3 I think almost constantly about major and minor defects in myself.

12. Thoughts of Death or Suicide:
- ☐ 0 I do not think of suicide or death.
- ☐ 1 I feel that life is empty or wonder if it's worth living.
- ☐ 2 I think of suicide or death several times a week for several minutes.
- ☐ 3 I think of suicide or death several times a day in some detail, or I have made specific plans for suicide or have actually tried to take my life.

13. General Interest
- ☐ 0 There is no change from usual in how interested I am in other people or activities.
- ☐ 1 I notice that I am less interested in people or activities.
- ☐ 2 I find I have interest in only one or two of my formerly pursued activities.
- ☐ 3 I have virtually no interest in formerly pursued activities.

During the past seven days...

14. Energy Level:
- ☐ 0 There is no change in my usual level of energy.
- ☐ 1 I get tired more easily than usual.
- ☐ 2 I have to make a big effort to start or finish my usual daily activities (for example, shopping homework, cooking or going to work).
- ☐ 3 I really cannot carry out most of my usual daily activities because I just don't have the energy.

15. Feeling Slowed Down:
- ☐ 0 I think, speak, and move at my usual rate of speed.
- ☐ 1 I find that my thinking is slowed down or my voice sounds dull or flat.
- ☐ 2 It takes me several seconds to respond to most questions and I'm sure my thinking is slowed.
- ☐ 3 I am often unable to respond to questions without extreme effort.

16. Feeling Restless:
- ☐ 0 I do not feel restless.
- ☐ 1 I'm often fidgety, wringing my hands, or need to shift how I am sitting.
- ☐ 2 I have impulses to move about and am quite restless.
- ☐ 3 At times, I am unable to stay seated and need to pace around.

Table 13-6 Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR_{16}) Scoring Instructions

1. Enter the highest score on any one of the 4 sleep items (items 1 to 4)

   Enter the highest score on any one of the 4 weight items (items 6 to 9)

   Enter the highest score on either of the two psychomotor items (items 15 and 16)

2. There will be one score for each of the nine Major Depressive Disorder symptom domains
3. Add the scores of the 9 items (sleep, weight, psychomotor changes, depressed mood, decreased interest, fatigue, guilt, concentration, and suicidal ideation) to obtain the total score; total scores range from 0 to 27
4. 0â€“5: no depressive symptoms endorsed; 6â€“10: mild symptoms; 11â€“15: moderate symptoms; 16â€“20: severe symptoms; 21â€“27: very severe symptoms

Anxiety Disorders

Anxiety disorders have the highest prevalence rates in the U.S. Lifetime prevalence rates approximate 30 percent, and women are 1.6 times more likely to be diagnosed than men (Kessler, 2005). For women, the key transitions of menarche, pregnancy, and menopause may cause anxious feelings, because of the perceived irreversible life changes they may herald (see Chap. 21, Psychosocial Changes) (Bibring, 1959). Criteria established in the DSM-IV-TR may provide guidelines to help distinguish anxiety disorder from normally expected worries (Tables 13-7 and 13-8).

Table 13-8 Diagnostic Criteria for Generalized Anxiety Disorder
A. Excessive anxiety and worry occurring more days than not for at least 6 months, about a number of events or activities
B. The person finds it difficult to control the worry
C. The anxiety and worry are associated with three or more of the following six symptoms: 1. Restlessness or feeling keyed up or on edge 2. Being easily fatigued 3. Difficulty concentrating or mind going blank 4. Irritability 5. Muscle tension 6. Sleep disturbance
D. The focus of the anxiety and worry is not confined to features of another psychiatric disorder (e.g. worry about having a panic attack [Panic Disorder]; being embarrassed in public [Social Phobia]; gaining weight [Anorexia Nervosa])
E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning
F. The disturbance is not due to the direct physiologic effects of a substance or a general medical condition and does not occur exclusively during a Mood Disorder or a Psychotic Disorder

Adapted from American Psychiatric Association, 2000a, with permission.

Alcohol and Substance Disorders

In the United States, the lifetime prevalence of alcohol and substance disorders approximates 15 percent. This diagnosis is twice as likely in males, although rates in women are increasing (Kessler, 2005). Indicators of substance misuse are found in Tables 13-9 and 13-10. Often these disorders co-occur with depression and anxiety. In depth discussion of these issues is beyond the scope of this chapter, but additional information regarding alcohol and other commonly abused substances, including prescription medications, can be found at www.nida.nih.gov .

Table 13-9 Diagnostic Criteria for Substance Dependence
A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three or more of the following, occurring at any time in the same 12-month period:
(1) Tolerance, defined by either (a) a need for markedly increased amounts of the substance (b) markedly diminished effect with continued use of the same amount of the substance
(2) Withdrawal, manifested by (a) characteristic withdrawal syndrome for the substance (b) the same or a closely related substance is taken to relieve or avoid withdrawal symptoms
(3) The substance is often taken in larger amounts or over a longer period than is intended
(4) There is a persistent desire or unsuccessful efforts to cut down or control substance use
(5) A great deal of time is spent in activities necessary to obtain the substance, use the substance (visiting multiple doctors or driving long distances), or recover from its effects
(6) Important social, occupational, or recreational activities are given up or reduced because of substance use
(7) Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance

Adapted from American Psychiatric Association, 2000a, with permission.

Table 13-10 Diagnostic Criteria for Substance Abuse
A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one or more of the following, occurring within a 12-month period (1) Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household) (2) Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use) (3) Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct) (4) Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with a spouse about the consequences of intoxication or getting into physical fights)
B. The symptoms have never met the criteria for Substance Dependence for this class of substance

Adapted from American Psychiatric Association, 2000a, with permission.

EATING DISORDERS

Eating disorders are classified by DSM-IV-TR as anorexia nervosa (AN), bulimia nervosa (BN), and eating disorder not otherwise specified (Tables 13-11 and 13-12). The core symptoms of both anorexia and bulimia are preoccupation with weight gain and excessive self-evaluation of weight and body shape. These disorders are 10 to 20 times more common in females than in males, particularly in those aged 15 to 24 years (Kaplan, 1998; Lucas, 1991). During adolescence, an estimated 4 percent of girls have some form of eating disorder, and approximately 0.3 percent suffers from anorexia nervosa. Anorexia usually begins early in adolescence and peaks around ages 17 to 18 years. Bulimia nervosa is more prevalent than anorexia but typically has a later onset (Hoek, 1998, 2006).

Table 13-11 Diagnostic Criteria for Anorexia Nervosa
A. Refusal to maintain body weight at or above a minimally normal weight for age and height (less than 85% of that expected)
B. Intense fear of gaining weight or becoming fat, even though underweight
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low weight
D. In postmenarcheal females, amenorrhea
Restricting Type: No binge-eating or purging behaviors
Binge-Eating/Purging Type: Binge-eating and self-induced vomiting, or the misuse of laxatives, diuretics, or enemas

Adapted from American Psychiatric Association, 2000a, with permission.

Table 13-12 Diagnostic Criteria for Bulimia Nervosa
A. Recurrent episodes of binge eating 1. Eating, in a discrete period of time, an amount of food definitely larger than most people would eat in a similar period of time under similar circumstances 2. A sense of lack of control over eating during the episode
B. Recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
C. Binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months
D. Self-evaluation is unduly influenced by body shape and weight
E. The disturbance does not occur exclusively during episodes of Anorexia Nervosa
Purging Type: Regularly engaging in purging behaviors
Nonpurging Type: Compensatory behaviors are inappropriate, such as fasting or excessive exercise, but do not include vomiting or the misuse of laxatives

Adapted from American Psychiatric Association, 2000a, with permission.

Pathophysiology

The exact etiology of eating disorders is unknown. However, evidence suggests that there is a strong familial aggregation for eating disorders (Stein, 1999). In the restricting type of AN, the concordance rate among monozygotic twins has been shown to approximate 66 percent, and in dizygotic twins it is 10 percent (Treasure, 1989).

Various biologic factors have been implicated in the development of eating disorders. Abnormalities in neuropeptides, neurotransmitters, and the hypothalamic-pituitary-adrenal and hypothalamic-pituitary-gonadal axes are reported (Stoving, 1999, 2001). In addition, psychological and psychodynamic factors related to an absence of autonomy are thought to influence obsessive preoccupations (Kaplan, 1998). Although eating disorders are believed to be a Western cultural phenomenon, rates of eating disorders are also increasing in nonwestern cultures (Fichter, 2004).

Diagnosis

ANOREXIA NERVOSA (AN)

This disorder is divided into two subtypes: (1) a restricting type and (2) a bulimic type, which is distinct from bulimia nervosa. Symptoms begin in the form of unique eating habits that become more and more restrictive. Advanced symptoms may include extreme food intake restriction and excessive exercise. Up to 50 percent of anorectics also show bulimic behavior, and these types may alternate during the course of anorexic illness. Bulimic-type anorectics have been found to engage in two distinct behavior patterns: those who binge and purge and those who solely purge.

Individuals with anorexia commonly defend their eating behaviors upon confrontation and rarely recognize their illness. They increasingly isolate themselves socially as their disorder progresses. Multiple somatic complaints such as gastrointestinal symptoms and cold intolerance are common. In the disorder's later stages, weight loss becomes more apparent and medical complications may prompt patients to seek help. These individuals often present with dental problems, general nutritional deficiency, electrolyte abnormalities (hypokalemia and alkalosis), and decreased thyroid function. Electrocardiogram changes such QT prolongation (bradycardia) and inversion or flattened T waves may be noted. Rare complications include gastric dilation, arrhythmias, seizure, and death.

BULIMIA NERVOSA (BN)

This disorder is identified by periods of uncontrolled eating of high-calorie foods (binges), followed by self-induced vomiting (purging). Moreover, bulimic women may often misuse laxatives or diuretics. Unlike anorexia, those with bulimia often recognize their maladaptive behaviors.

Most bulimics have normal weights, although their weight may fluctuate. Thus, physical findings may be more subtle. One of the most characteristic signs is knuckle calluses found on the dorsum of the dominant hand. Termed *Russell sign,* calluses form in response to repetitive contact with upper teeth and acidic stomach contents during purging (Strumia, 2005).

Comorbidity of Eating Disorders

Anorexia nervosa and bulimia nervosa are complex disorders, affecting both psychological and physical systems. These eating disorders often are accompanied by comorbid depression and anxiety symptoms. Rates of mood symptoms approximate 50 percent, and anxiety symptoms 60 percent (Braun, 1994). Simple phobia and obsessive-compulsive behaviors may also coexist. In many cases, patients with anorexia appear to have rigid, perfectionistic personalities and have low sexual interest. Patients with bulimia often display sexual conflicts, problems with intimacy, and impulsive suicidal tendencies (American Psychiatric Association, 2000b).

Prognosis of Eating Disorders

There are limited data concerning the long-term physical and psychological prognosis of women with eating disorders. Most may symptomatically improve with aging. However, complete recovery from anorexia nervosa is rare, and many continue to have distorted body perceptions and peculiar eating habits. Overall, the prognosis for bulimia is better than for anorexia.

Treatment of Eating Disorders

Treatment of eating disorders involves a multidisciplinary approach. The American Psychiatric Association practice guidelines for eating disorders include: (1) nutritional rehabilitation, (2) psychosocial treatment that includes individual and family therapies, and (3) pharmacotherapeutic treatment of concurrent psychiatric symptoms (American Psychiatric Association, 2000b). An online resource for information and support is provided by the National Eating Disorder Association, www.edap.org . However, health care providers should also be aware of proâ€"eating disorders websites, which may enable anorexic behaviors (Norris, 2006).

PREMENSTRUAL DISORDERS

Frequently, women of reproductive age experience symptoms during the late luteal phase of their menstrual cycle, and collectively these complaints are termed *premenstrual syndrome* (PMS) or *premenstrual tension* (PMT). Nearly 300 different symptoms have been reported and typically include both psychiatric and physical complaints (Table 13-13) (Halbreich, 2003a). For most women, these symptoms are self-limited. However, approximately 15 percent report moderate to severe symptoms that cause some impairment or require special consideration (Wittchen, 2002).

Premenstrual dysphoric disorder (PMDD) and *premenstrual dysphoria* (PMD) are independent clinical conditions that are identified

by an accompanying psychosocial or functional impairment. The degree of impairment is often equivalent to that seen in patients with minor depression or dysthymia (Halbreich, 2003b). Premenstrual dysphoric disorder carries significant functional impairment. Therefore, this diagnosis should be reserved for those who meet the strict DSM-IV-TR criteria (American Psychiatric Association, 2000a). In practice, however, the diagnosis of PMDD is often confused with PMD, particularly if a woman's complaints match some PMDD criteria. The prevalence of true PMDD in the general female population is thought to be 3 to 8 percent (Wittchen, 2002).

Pathophysiology of Premenstrual Syndrome

The exact causes of premenstrual disorders are unknown, although several different biologic factors have been suggested. Of these, estrogen and progesterone, as well as the neurotransmitters, γ-amino butyric acid (GABA) and serotonin, are frequently studied (Halbreich, 2003b).

SEX STEROIDS

Premenstrual syndrome is cyclic. Symptoms begin following ovulation and resolve with menses. They are less common in women with surgical oophorectomy or drug-induced ovarian hypofunction such as with gonadotropin-releasing hormone (GnRH) agonists. Moreover, women with anovulatory cycles rarely report PMS symptoms. For these reasons, research of PMS pathophysiology has focused on the sex steroids, estrogen and progesterone.

Central Nervous System Interaction

Estrogen and progesterone are neuroactive steroids and influence the central nervous system (CNS) neurotransmitters: serotonin, noradrenaline, and GABA. The predominant action of estrogen is neuronal excitability, whereas progestins are inhibitory (Halbreich, 2003b).

Specifically, premenstrual syndrome is believed to be in part associated with neuroactive progesterone metabolites. Of these, allopregnanolone is a potent modulator of GABA receptors, and its effects mirror those of low-dose benzodiazepines, barbiturates, and alcohol. These effects may include loss of impulse control, negative mood, and aggression or irritability (Backstrom, 2003). Wang and colleagues (1996) noted fluctuations in serum allopregnanolone across the various menstrual cycle phases. These changes were implicated with PMS symptom severity. However, this finding has not been consistently replicated by others (Rapkin, 1997; Schmidt, 1994; Sundstrom, 1998). Moreover, the significance of serum level changes relative to brain concentrations changes remains unclear.

SEROTONIN

Evidence also supports a role for serotonergic system dysregulation in the pathophysiology of PMS. Decreased serotonergic activity has been noted in the luteal phase. Moreover, trials of serotonergic treatments have shown symptom reduction in women with PMS (Cohen, 2004; Halbreich 2002a; Yonkers, 1996).

RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

Sex steroids also interact with the renin-angiotensin-aldosterone system (RAAS) to alter electrolyte and fluid balance. The anti-mineralocorticoid properties of progesterone and possible estrogen activation of the RAAS system may explain PMS symptoms of bloating and weight gain.

Diagnosis of Premenstrual Syndrome

Women with PMS usually present with complaints from multiple systems, and these symptoms display temporal association with the menstrual cycle luteal phase. Symptoms must begin at least 5 days (American College of Obstetricians and Gynecologists [ACOG] criteria) or 1 week (DSM-IV-TR) before menses, and remit within 4 days (ACOG criteria) or a few days (DSM-IV-TR) after menses onset (American College of Obstetricians and Gynecologists, 2000). Evaluation of women complaining of PMS symptoms includes prospective daily symptom rating for at least two or three menstrual cycles. However, Borenstein and associates (2007) found that results from the Daily Record of Severity of Symptoms (Table 13-13) obtained on the first day of menses could be used for initial screening.

In certain instances, PMS symptoms may be an exacerbation of underlying primary psychiatric condition(s). Thus, during

evaluation, other common psychiatric conditions such as depression, dysthymia, and anxiety disorders should be excluded. Additionally, other medical conditions that have a multisystem presentation should be considered. These include hypothyroidism, systemic lupus erythematosus, endometriosis, anemia, fibromyalgia, chronic fatigue syndrome, fibrocystic breast disease, irritable bowel syndrome, and migraine.

Treatment of Premenstrual Syndrome

Commonly used treatments for PMS have focused on either symptom reduction or modification of underlying hormonal dysregulation. Clinicians may consider treatment options for mild to moderate cases. However, if treatment fails or if symptoms are severe, then psychiatric referral may be indicated.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Most psychotropic medications are effective in reducing psychological symptom severity. Several well-controlled trials of selective serotonin reuptake inhibitors (SSRIs) have shown these drugs to be efficacious and well tolerated (Cohen, 2002; Halbreich 2002b; Yonkers, 1996, 1997). Standard dosages of SSRIs with either an intermittent or continuous dosing strategy are now considered primary therapy for psychological symptoms of PMS (Table 13-14). In addition, short-term use of anxiolytics such as alprazolam or buspirone offer added benefits to some women with prominent anxiety. However, in prescribing anxiolytics, caution should be taken in women with prior history of substance abuse.

Table 13-14 List of Common Psychotropic Medications

Drug Class	Indication	Examples	Brand Name	Commonly Reported Side Effects	Pregnancy Category
Selective serotonin reuptake inhibitors (SSRIs)	Depressive, anxiety, and premenstrual disorders	Fluoxetine Citalopram Escitalopram Sertraline Paroxetine Fluvoxamine	Prozac, Sarafem Celexa Lexapro Zoloft Paxil Luvox	Nausea, headache, insomnia, diarrhea, dry mouth, sexual dysfunction	Class C, Paroxetine is Class D
Serotonin noradrenergic reuptake inhibitors (SNRIs)	Depressive, anxiety, and premenstrual disorders	Bupropion SR, XL Venlafaxine XR Duloxetine	Wellbutrin Effexor Cymbalta	Dry mouth, anxiety, agitation, dizziness, somnolence, constipation	Class C

	Sleep agents	Zaleplon Zolpidem Ramelteon	Sonata Ambien Rozerem	Headache, somnolence, amnesia, fatigue	Class C

SR = sustained release; XR/XL = extended release.

ESTROGEN AND PROGESTERONE

Because gonadal hormonal dysregulation is implicated in the genesis of PMS symptoms, both estrogen and progesterone therapies have been evaluated. However, efficacy is highly variable with progesterone and to some extent with estrogen. Ford and colleagues (2006) reviewed randomized controlled studies that assessed progesterone treatment efficacy for PMS. They found "only a little good evidence" for progesterone use in treating premenstrual syndrome. Other studies evaluating estrogen, progesterone, and progesterone-blocking agent administration during the luteal phase have reported worsening patient PMS symptoms (Schmidt, 1998). Thus, due to the heterogeneous actions of estrogen and progesterone in PMS, it is difficult to predict who would likely benefit from exogenous treatment with these hormones.

In addition, data are limited in support of combination oral contraceptive (COC) pills for this indication. However, a unique COC, containing the spironolactone-like progestin drospirenone, (Yasmin, Berlex, Montville, NJ) shows preliminary evidence of therapeutic benefits for PMS symptoms (Freeman, 2001). Larger studies, however, are needed to confirm these findings.

OTHER AGENTS

Prostaglandin inhibitors offer benefits through their anti- inflammatory effects. Agents such as ibuprofen and naproxen sodium are commonly used for cramping and headaches associated with PMS (see Table 10-2). In addition, diuretics may be prescribed to alleviate fluid retention and leg edema. Spironolactone and dyazide (combined hydrochlorothiazide and triamterene) are commonly used agents. However, potential side effects are orthostatic hypotension and hypokalemia.

Gonadotropin-releasing hormone agonists and synthetic androgens such as danazol alleviate symptoms by suppressing ovulation. However, the poor tolerability of these therapies are weighed against the potential benefits in women with premenstrual disorders (see Chap. 9, GnRH Agonists).

Diet can aggravate PMS and foods and beverages high in sugar and caffeine may worsen symptoms (Johnson, 1995). In contrast, vitamins such as pyridoxine (vitamin B_6) and vitamin E may offer benefits. Pyridoxine is a cofactor to tryptophan hydroxylase, which is the key enzyme in serotonin synthesis (Wyatt, 1999). The recommended dose of pyridoxine is 50 to 100 mg/d orally, but doses exceeding 100 mg/d should be avoided to prevent pyridoxine toxicity. In smaller trials, minerals such as calcium and magnesium have shown benefits. Magnesium in combination with vitamin B_6 appears to reduce anxiety-related premenstrual symptoms (De Souza, 2000). Calcium benefits are possibly through calcium deficiencyâ€"related symptoms such as muscle cramps (Thys-Jacobs, 2000).

PREGNANCY AND POSTPARTUM DISORDERS

During pregnancy and the postpartum period, changing hormone levels, physical alterations, fatigue, and new social responsibilities often lead to psychological stress. Although pregnancy was previously viewed as protective against depression, some women experience the first onset of depression or other psychiatric disorders during this time. Moreover, pregnancy has been associated with relapse in psychotic disorders, and women with a history of depression are at the highest risk for suffering an episode during pregnancy or the postpartum period (Cohen, 2006a; O'Hara, 1996). Accordingly, clinicians should inquire specifically about any history of psychiatric distress, as this is the dominant risk factor for any psychiatric disorder during the perinatal period.

For the most part, psychiatric disorders during pregnancy have a course or presentation similar to those same disorders in nonpregnant women. For this reason, diagnostic criteria for psychiatric disorders do not change, but often the specifier "postpartum onset" is included in the diagnosis.

Mood Disorders in the Perinatal Period

DEPRESSION DURING PREGNANCY

Risks for Depression in Pregnancy

The prevalence of depression during pregnancy has been estimated to be highest (11 percent) in the first trimester, falling to 8.5 percent in the second and third trimesters. Most investigations of risk factors and predictors have been directed toward postpartum depression. However, a few studies have found that depression during pregnancy is often associated with adverse life events, chronic stress, limited social support, and past or current sexual or physical abuse (O'Hara, 1996).

Diagnosis of Depression in the Perinatal Period

The Edinburgh Postnatal Depression Scale (EPDS) is a screening measure specifically developed to screen for and assess severity of depressive symptoms during pregnancy and the postpartum (Cox, 1987). Unlike other depression screens that include symptoms that are also characteristic of pregnancy itself (appetite, weight change, sleep disturbance, and fatigue), this scale concentrates on the neurovegetative symptoms that are more descriptive of depression. Available in a number of languages, the EPDS is an efficient way for a clinician to identify patients that are at risk for being depressed both during pregnancy and postpartum. It is available through the American Academy of Pediatrics at: http://www.dbpeds.org/media/edinburghscale.pdf .

Treatment of Depression in Pregnancy

No antidepressant has been approved by the U.S. Food and Drug Administration (FDA) during pregnancy (Kornstein, 2001). However, SSRIs are commonly used antidepressants, and the FDA describes them as category C drugs except for paroxetine (Paxil, GlaxoSmithKline, Philadelphia, PA), which is category D (see Table 13-14). Recent evidence has caused concern regarding the safe use of SSRIs during pregnancy. In July 2006, the FDA issued a Public Health Advisory recommending a careful risk assessment during pregnancy. These drugs have been linked to persistent pulmonary hypertension in the newborn (PPHN). In addition, in 2005, the FDA issued a Public Health Advisory stating that paroxetine may increase the risk of congenital cardiac malformations.

However, women who discontinue antidepressant medication during pregnancy relapse into depression significantly more frequently than women who maintain their pharmacologic treatment (Cohen, 2006b). In addition, suicide remains a significant proportion of pregnancy-associated deaths (Shadigian, 2005). Thus, a clinician must assess the risk of relapse in a severely depressed women against potential risk to the newborn (Wisner 2000).

Nonpharmacologic approaches have also been used as potential treatment options during pregnancy. These include acupuncture, sleep cycle manipulation, cognitive-behavioral therapy, and interpersonal psychotherapy (Carter, 2004; Manber, 2004; Parry, 2000; Spinelli, 2003).

DEPRESSION IN THE POSTPARTUM

Risks

Depression after childbirth has largely been divided into three categories: "postpartum blues", postpartum depression, and

postpartum psychosis. The strongest predictors of postpartum depression include prior psychopathology, poor marital relationship, low levels of social support, and stressful life events in the previous 12 months (O'Hara, 1996).

CLASSIFICATION

Postpartum Blues

This transient state of heightened emotional reactivity can develop in up to 50 percent of women. The onset is 2 to 14 days after childbirth, and its duration is less than 2 weeks (Gaynes, 2005). Blues generally require no intervention. Rest and social support contribute significantly to remission. However, postpartum blues do constitute a significant risk factor for subsequent depression during the postpartum.

Postpartum Depression

According to the DSM-IV-TR, postpartum depression refers to the diagnosis of major depressive disorder within 4 weeks after childbirth. However, in research and most clinical settings, any depression developing within 12 months following childbirth is considered to have postpartum onset. With this definition, the prevalence of postpartum depression approximates 15 percent in postpartum women (Gaynes, 2005).

Postpartum depression warrants careful assessment by a mental health professional, as treatment should be initiated immediately to minimize impaired caregiving. Infants of depressed mothers have exhibited cognitive, temperamental, and developmental differences from infants of nondepressed mothers (Dawson, 1992; Murray, 1992; Whiffen, 1989). Selective serotonin reuptake inhibitors are usually first-line agents, although caution is necessary in breast feeding mothers. In addition, a number of psychosocial interventions have demonstrated efficacy in treating postpartum depression. Of these, the most significant effects have been achieved with cognitive-behavioral therapy and group therapy (Bledsoe, 2006; Boath, 2001). Additionally, Postpartum Support International is an excellent resource for information for both clinicians and patients. Information can be obtained at www.postpartum.net .

Postpartum Psychosis

This condition develops in less than 2 percent of new mothers, and its onset is generally within 2 weeks of childbirth (Gaynes, 2005). The risk for this severe form of depression is increased for women who have had prior mood disorders. Particularly, prior postpartum psychosis increases by 30 to 50 percent a woman's risk with subsequent deliveries (American Psychiatric Association, 2000a). Evaluation and antipsychotic pharmacologic treatment is essential for these women. Hospitalization is often indicated until the safety of mother and infant is assured.

Other Psychiatric Disorders in the Perinatal Period

Clinicians most often focus on mood disorders during the perinatal period. However, other psychiatric illnesses such as anxiety disorders, bipolar disorders, and schizophrenia may also present.

Of these, bipolar disorders and schizophrenia are serious, recurrent psychiatric illnesses that require pharmacologic treatment. Treatment planning is critical with such patients, and decisions should always be made in collaboration with a psychiatric professional. A careful balance must be struck between minimizing medication risk to the fetus and maternal risk from untreated or undertreated disease.

Perinatal Loss

Perinatal loss did not become a subject of professional research until the 1970s. Although many studies have focused on identifying factors that modify grieving styles, a few have focused on interventions with families after perinatal loss. Study results showed that health care providers were most helpful if they spoke directly, used understandable language, and shared information that would provide parents a sense of control over their situation and would address their fears. Additional time with health professionals and a perception of being a priority was also important to parents (DiMarco, 2001).

Since grief is individual, no generalizations can be made concerning patient support in such situations. Thus, a clinician must ask a patient what she needs and wants. Couples therapy may be helpful if mother and father find it difficult to grieve congruently.

Family therapy may be indicated if other children need support to process the loss and their parents' grief. Many hospitals provide support groups, and several on-line resources are available. Specifically, the Hygeia Foundation (www.hygeia.org) and the National Perinatal Association websites (www.nationalperinatal.org) offer helpful resources.

MENOPAUSAL TRANSITION AND MENOPAUSE

Risks for Psychiatric Disorders during Menopausal Transition

Menopausal transition has long been investigated as a vulnerable period for emergence of mood symptoms. Anxiety, irritable mood, and sleep problems are more likely to develop in perimenopausal women than in premenopausal women (Bromberger, 2001; Freeman, 2006). Moreover, recent data suggest that rates of new-onset depression during menopausal transition are nearly twofold greater than premenopausal rates (Cohen, 2006a). This risk persists even after adjusting for sleep disturbances and vasomotor symptoms.

Other possible risks for depression and anxiety are a prior history of depression, severe premenstrual distress, presence of hot flashes, and disrupted sleep. Demographic predictors of increased risk during the menopausal period are lower educational status, African-American ethnicity, unemployment, and major life stressors (Bromberger, 2001; Freeman, 2006; Maartens, 2002). Moreover, psychosocial issues include a woman's recognition that her reproductive years are ending and that her children will leave to establish their own lives. Developmentally, many women are transitioning from being focused on family to finding other avenues to invest time and energy.

Mood vulnerability during menopausal transition is believed to follow erratic physiologic fluctuations in reproductive hormones. A fuller discussion of these hormones as they relate to mood changes during this transition is found in Chapter 21, Psychosocial Changes.

Evaluation during Menopausal Transition

Women with psychological complaints warrant a comprehensive psychosocial inventory and risk factor assessment. Importantly, medical conditions may concurrently develop during this transition, may create psychological symptoms, and should be excluded. Specifically, thyroid function should be evaluated.

Treatment of Mood Symptoms during Menopausal Transition

The approach to treating mood symptoms involves both pharmacotherapy and psychotherapy. Recommended psychotropic medications are selective serotonin reuptake inhibitors and selective noradrenergic reuptake inhibitors (e.g., venlafaxine [Effexor, Wyeth, Madison, NJ]). These agents are good options for women who do not wish to take hormone therapy. Additional benefits include alleviation of vasomotor symptoms and improved sleep.

Studies suggest that short-term administration of estrogen is an option for perimenopausal women with depressive symptoms (Soares, 2001). However, this benefit should be weighed against safety concerns raised in the Women's Health Initiative (WHI) Study (see Chap. 22). The psychotropic role of estrogen-progesterone preparation in postmenopausal women remains unclear.

LATE LIFE

According to estimates by the U.S. Census Bureau, the number of older Americans will significantly increase over the next decade as the "Baby Boomer" generation ages. By 2030, nearly 20 percent of the population will be older than 65 years (He, 2005). Psychosocial issues addressed are significantly different for these women. Stressors may include diminished mental and physical function as well as loss of partner, family, or friends. Erikson identified the task of this final developmental stage of life as one of consolidation and integration. In this model, women retrospectively examine their lives. They may manage their last years with integrity and with satisfaction in a life well lived, or may suffer despair, feeling that all was in vain.

Mental Disorders in the Elderly

According to the 2000 U.S. census, functionally impairing mental disorders affected 11 percent of adults aged 65 to 74 and 10 percent of those older than 74 (He, 2005). Of these disorders, depression, anxiety, late-onset psychotic and paranoid disorders, and alcoholism are those most likely to be observed in a clinical practice (Zarit, 1998). However, the prevalence of depression is generally thought to be lower in postmenopausal women compared with reproductive-aged women. Moreover, most studies suggest that the gender gap between rates of depression closes in late life. As in the general population, anxiety is the most common psychiatric disorder in the elderly (Zarit, 1998).

Evaluation of Psychiatric Disorders in Late Life

If a psychiatric disorder is suspected, careful evaluation is required to exclude underlying medical causes for these changes. For example, depression may be a comorbid disorder with or an early symptom of Alzheimer and Parkinson disease (Polidori, 2001). Alternatively, depression, anxiety, and psychosis may also result from single medications or medication combinations.

Specific screening questionnaires for depression have been developed for the elderly, such as the Geriatric Depression Scale (Brink, 1982). This screening tool is available in various languages at: http://www.stanford.edu/~yesavage/GDS.html . In addition, neuropsychological evaluation is helpful to discriminate between the source and nature of mood symptoms and cognitive impairment.

Treatment of Psychiatric Disorders in Late Life

Recognizing the natural decline in serotonin levels with aging, many gerontologists prescribe SSRIs for their patients. However, communication between all treating physicians to coordinate medications and minimize interactions is particularly important for elderly patients.

Psychosocial treatments are often helpful for the patient and, where applicable, her caregivers. Cognitive-behavioral therapy and interpersonal therapy have both been found efficacious with the elderly. Moreover, family therapy can be of great value to those struggling with end-of-life issues, functional impairments, multiple losses, and caregiver burden. Social workers are also of tremendous value if a patient and family need to locate additional resources for care.

A meta-analysis of 89 treatment studies found that pharmacotherapy and psychotherapy achieved comparable results in treatment of depression. Thus, treatment planning may be individualized and should assess patient preference, contraindications, and treatment access (Pinquart, 2006).

ADDITIONAL DISORDERS THAT PRESENT ACROSS THE LIFE SPAN

Somatoform Disorders

Recurrent, multiple, often unexplained physical symptoms are hallmark features of somatoform disorders. These disorders are common, and their estimated prevalence in general clinical practice is 16 percent (de Waal, 2004). Their prevalence may be even higher in specialty clinics such as pain management clinics.

Somatoform disorders are complex and poorly understood. However, symptoms cause significant distress and/or impairment in various domains of an affected individual's life. Moreover, one in four somatoform patients suffer from comorbid anxiety and depressive symptoms. Thus, a multidisciplinary approach is often required to effectively manage these women's symptoms.

SEXUAL ASSAULT

Sexual assault is a crime of violence, often motivated by aggression and rage, with the assailant using sexual contact as a weapon for power and control. Sexual assault can include a range of coercive behaviors ranging from kissing, fondling, and molestation, to rape or attempted rape. Linden (1999) defines sexual assault as "an event that occurred without the victim's consent, involved the use of force or the threat of force, and involved actual or attempted penetration of the victim's vagina, mouth, or rectum".

According to recent statistics, one in eight women will be raped during her lifetime, and 39 percent will be sexually assaulted more than once (Kilpatrick, 1992). Many rapes are unreported, because of a victim's feelings of shame and guilt. Alternatively, a victim may not define the event as rape (e.g., spousal and date rape).

Well-known sequelae of rape include isolation, depression, anxiety, somatic symptoms, suicide attempts, and posttraumatic stress disorder (PTSD). The experience has a strong effect on the victim's subsequent health and thus is a major public health issue. Importantly, in caring for sexual assault victims, clinicians should be familiar with the complex array of reactions (emotional and physical), common injuries, and elements of proper evaluation and treatment of these patients.

Common Physical Findings with Sexual Assault

Initial evaluation of a sexual assault victim should concentrate on identifying serious injuries. Although 70 percent of rape victims sustain no obvious physical injuries, 24 percent sustain minor injuries, and up to 5 percent sustain major nongenital injuries. Although death is rare (0.1 percent sustain fatal injuries), the fear of death during an assault is one of the most intense reactions (Deming, 1983; Marchbanks, 1990). The most common nongenital injuries in sexual assault victims include bruises, cuts, scratches, and swelling (81 percent); internal injuries and unconsciousness (11 percent); and knife or gunshot wounds (2 percent) (Sommers, 2001). In the genital area, the posterior fourchette is the area most often injured.

Once life-threatening injuries are excluded, a woman should be moved to a quiet, private setting for further evaluation. A systematic, thorough, but compassionate approach to obtaining a history and collecting evidence is essential for appropriate treatment of the victim and for future prosecution of her assailant.

Rape Examination and Legal Documentation

Although valid evidence may be collected up to 5 days after sexual assault, immediate examination increases the opportunity to obtain valuable physical evidence (Table 13-15). Consent is obtained prior to physical and genital examination and evidence collection. This step helps to re-establish a victim's sense of control and is essential for entry of evidence in a court of law (Plaut, 2004). Providers should emphasize that vital information may be lost if evidence is not collected early, and that evidence collection does not commit a victim to pressing criminal charges (Linden, 1999). Moreover, a patient should be counseled that she may terminate an examination if it is too emotionally or physically painful.

Table 13-15 Important Elements of Physical Examination and Evidence Collection Following Sexual Assault
Physical examination
General appearance
Affect/emotional status
Complete examination of head, body, and extremities, with body diagram of injuries
Pelvic examination, with colposcopy if available to exclude lower reproductive tract trauma
Elements of evidence collection
Swabs and smears of involved orifices
Saliva sample from the patient
Fingernail scrapings from the patient, if the victim scratched the assailant's skin or clothing
Clothing collected in labeled paper bags
Head hair combings, head hairs cut or pulled from patient
Pubic hair combings, pubic hair cut or pulled from patient
Blood sample for patient blood typing

Most states have standardized kits for evidence collection and storage in which kits may be locked to ensure that legal evidence procedures are maintained. Documentation of all physical injuries is essential, and objective evidence of trauma (even minor) is associated with increased chances of successful prosecution. Clothing is collected as a patient undresses on a white sheet and placed in properly labeled bags. Any debris, such as hair, fibers, mud, or leaves should also be collected.

Evidence gathering includes a sample of the patient's saliva and swabs of all involved orifices. A thorough pelvic examination with evidence collection is essential, even if there are no complaints of genital pain. Up to one third of victims can have traumatic genital injuries without symptoms. Common patterns of genital injury include tears of the posterior fourchette and fossa, labial abrasions, and hymenal bruising. Significant genital injuries are more common in postmenopausal or prepubertal victims. Colposcopy should be used if available because this technique increases detection of more subtle injuries of the cervix and vagina. Lenahan (1998) reported that the use of colposcopy increased genital trauma recognition from 6 percent to 53 percent. In addition, a Wood lamp may aid identification of semen on the skin, which then should be collected with moistened cotton swabs. A blood sample is collected for typing, to differentiate the blood type of the victim from that of the assailant. After evidence is collected, it is signed, sealed, and locked in a secure place (Rambow, 1992).

Treatment Following Sexual Assault

PREGNANCY PREVENTION

Medication prophylaxis to prevent pregnancy and common sexually transmitted diseases is provided to women following sexual assault. The risk of rape-related pregnancy is estimated at 5 percent per rape among reproductive-aged victims (Holmes, 1996). Most of these pregnancies, unfortunately, occur in adolescents, who are often the victims of incest and who never report the incident or receive medical attention. Because of variation in a woman's menstrual cycle, pregnancy prophylaxis, also termed *emergency contraception,* should be offered to all victims (see Chap. 5, Emergency Contraception). Prophylaxis can be administered for up to 72 hours after rape, but is most effective in the first 24 hours (Table 13-16). In some studies, prophylaxis

was effective for up to 5 days following rape.

Table 13-16 Pregnancy and Sexually Transmitted Disease Prevention Following Sexual Assault
Testing
Pregnancy test (urine or serum)
Hepatitis antibodies
Venereal Disease Research Laboratory (VDRL) test (consider)
Cultures for Neisseria gonorrhoeae and Chlamydia trachomatis
Microscopic evaluation of vaginal discharge saline prep
Treatment
Plan B: levonorgestrel 0.75 mg, one pill orally every 12 hours for two doses
Ceftriaxone 125 mg intramuscularly, single dose
Azithromycin 1 g orally, single dose
Optional treatment
Hepatitis B vaccination (see Table 1-1).
Metronidazole 2 g orally, single dose
Human immunodeficiency virus prophylaxis with zidovudine, 200 mg orally three times daily and lamivudine, 150 mg orally twice daily for 4 weeks

A negative pregnancy test to exclude preexisting pregnancy should be confirmed before administering emergency contraceptive methods. Side effects of estrogen/progestin combinations include nausea (in up to 50 percent of patients), and vomiting (in up to 20 percent), breast tenderness, and heavier menstrual period. With use of Plan B (levonorgestrel 0.75 mg, one pill taken orally every 12 hours for two doses), the risk of nausea is reduced to 23 percent and vomiting to 6 percent (Arowojolu, 2002). An antiemetic can be prescribed one-half hour prior to administration to decrease nausea.

Patients should be informed that their next menses may be delayed following this prophylaxis. Although current regimens are 74 to 89 percent effective, women should be counseled to return if their next menses is more than 1 to 2 weeks late (Yuzpe, 1982; Trussell, 1996; Task Force on Postovulatory Methods of Fertility Regulation, 1998).

SEXUALLY TRANSMITTED DISEASE PREVENTION

The risk of acquiring a sexually transmitted disease (STD) after rape has been estimated. The risk of developing trichomoniasis is approximately 12 percent; bacterial vaginosis, 12 percent; gonorrhea, 4 to 12 percent; chlamydial infection, 2 to 14 percent; syphilis, 5 percent; and human immunodeficiency virus (HIV) infection, <0.1 percent (Jenny, 1990; Katz, 1997; Schwarcz, 1990). However, these risks are difficult to predict and vary by geographic location, type of assault, assailant, and presence of preexisting infections. General recommendations describe antibiotic prophylaxis for hepatitis, gonorrhea, and chlamydia (see Table 13-16).

The fear of contracting HIV after sexual assault is common in survivors and is often the primary concern after a rape (Baker, 1990). However, prophylaxis against HIV remains controversial, given the low risk of transmission following a single sexual assault (Gostin, 1994). Although the Centers for Disease Control and Prevention (CDC) has no formal recommendations for HIV prophylaxis in this setting, many experts recommend offering prophylaxis to candidates who are willing to take the full course of

medications and comply with surveillance testing. The risks and side effects of these medications and need for close monitoring should be discussed with patients (Katz, 1997, 1998).

PSYCHOLOGICAL RESPONSE TO SEXUAL ASSAULT

Survivors of sexual assault may display an array of reactions that commonly include anxiety, agitation, crying, or a quiet, calm, and detached affect. In 1974, Burgess and Holmstrom first characterized the "rape trauma syndrome". They described two response phases to the trauma of sexual assault: (1) the acute disorganization phase, lasting several weeks, and (2) the reorganization phase, lasting from several weeks to years. During the acute phase, common initial emotional reactions include shock and disbelief, fear, shame, self-blame, humiliation, anger, isolation, grief, and loss of control. Somatic reactions may be common. During the reorganization phase, feelings of vulnerability, despair, guilt, and shame may continue. Symptoms may include nonspecific anxiety, somatic complaints, or depression.

SUBSEQUENT CARE FOLLOWING SEXUAL ASSAULT

Survivors should be referred to local rape crisis centers and encouraged to visit within 1 to 2 days. All sexual assault victims should receive medical evaluation at 1 to 2 weeks, and 2 to 4 months following their rape. During these visits, examination for STDs and blood testing for HIV and syphilis (rapid plasma reagin [RPR]) should be performed. Remaining hepatitis vaccinations are administered, if needed (see Table 1-1).

DOMESTIC VIOLENCE

Defining Domestic Violence

The terms *domestic violence* (DV), *gender-based violence,* or *violence against women,* encompasse a multitude of abuses directed at women and girls. The United Nations Declaration on the Elimination of Violence Against Women (United Nations General Assembly, 1993) defines violence as acts that cause, or have the potential to cause harm. Introduction of the term "gender based" emphasizes that the act is rooted in inequality between women and men (Krantz, 2005). *Intimate partner violence* (IPV) refers to harm inflicted by one intimate partner on the other, with the intention of causing pain or controlling the other's behavior.

Violence against women varies and includes wife battering, rape, sexual assault, incest, and elder abuse (Burge, 1997; Straka, 2006). Most victims know their assailant and have been assaulted more than once. The average length of victimization is 4 years for repeatedly raped women and for physically assaulted women (Tjaden, 2000).

Domestic Violence Statistics

The CDC National Center for Injury Prevention and Control estimates that nearly 5.3 million incidents of intimate partner violence occur each year among U.S. women aged 18 years and older. These incidents result in nearly 2 million injuries and 1,300 deaths nationwide every year. Three studies conducted in family practice settings found that the lifetime prevalence of husband-to-wife violence (slapping or worse) ranged from 36 to 44 percent (Elliott, 1995; Hamberger, 1992; Pence, 1993).

Risk Factors Associated with Domestic Violence

YOUNG ADULTHOOD

Aside from youth, few traits characterize women who are assaulted by violent men. Peters and colleagues (2002) analyzed data from 5,298 domestic violence reports. They found that women aged 16 to 24 years are at greatest risk for DV, a risk that was more than twice as great as the risk for women aged 25 to 34 years. Rates of domestic violence decreased throughout women's reproductive years and reached a nadir in women aged 65 or older. Hotaling and Sugarman (1986) in their review found only one consistent risk marker of being an abused wife. Witnessing violence as a child was a significant risk factor in 11 of 15 studies.

DOMESTIC VIOLENCE DURING PREGNANCY

Women should be screened for domestic violence during the perinatal period. Seven to 20 percent of pregnant women may be victims, and homicide is reported as the leading cause of death during pregnancy. Most cases result from partner abuse (Gazmararian, 1996; Shadigian, 2005). Therefore, screening for interpersonal violence is an important component of prenatal care. The Antenatal Psychosocial Health Assessment (ALPHA) is a questionnaire that evaluates psychosocial health during pregnancy and

contains sections that screen for domestic violence. This screening tool can be found at: http://dfcm.utoronto.ca/research/alpha/pdf/en/alphaformlarge.pdf .

DOMESTIC VIOLENCE IN LATE LIFE

The social and medical problem of elder abuse is escalating with an increasingly elderly population. Currently, an estimated 2 million older adults are mistreated annually, and 84 percent of cases are unreported (Jayawardena, 2006). Elder abuse is divided into seven categories by The National Center on Elder Abuse: physical, emotional, and sexual abuse; financial exploitation, neglect; self-neglect; and miscellaneous (Tatara, 1997). Of these categories, neglect is the most prevalent form of mistreatment. It occurs most often in the home and is perpetrated most frequently by family members. Identified risk factors are caregiver stress, patient cognitive impairment and need for assistance with daily life activities, conflicted family relationships, and poor social support.

Diagnosis

Women who have been assaulted are far more likely to seek help from their medical provider than from legal personnel, mental health professionals, or victim advocates. Victims of violence have an unusually high rate of medical use for years after the assault and may present with psychiatric and somatic complaints to their primary care provider (Koss, 1992). Although some clinicians may feel awkward asking patients, researchers agree that *the single most important thing a physician can do for a battered woman is to ask about violence* (Linden, 1999). Additionally, health care providers should ask about violence if they identify symptoms or behaviors that may be associated with victimization (Burge, 1997). These may include bruising, unexplained injuries, depression or anxiety, alcohol or drug abuse, unexplained chronic pain, isolation, inability to cope, limited access to care, noncompliance, husbands with extremely controlling behaviors or intense jealousy, or husbands with substance abuse.

Management of Domestic Violence

PATIENT VALIDATION AND REFERRAL

If a patient discloses domestic violence, a clinician should validate and normalize a patient's perspective. Patients should be counseled that many women have assault experiences, that most are afraid to confide these, that memories about the experience can be painful, and that a fear of future assaults is a reasonable fear. Following disclosure, a clinician should express concern for the woman's health and safety and convey a willingness to discuss relationship issues at any time. Moreover, information describing community resources should be offered. The National Domestic Violence Hotline (1-800-799-SAFE [7233]) is a nonprofit telephone referral service, with access to more than 5,000 women's shelters nationally.

DOCUMENTATION

Battery is a crime, yet few states specifically require reporting of domestic violence. A small number of states require mandatory arrest of batterers, and a few jurisdictions aggressively pursue cases of domestic violence. Accordingly, each clinician should know their state laws to properly and adequately inform their patients. In addition, providers should thoroughly document physical findings of violence. Such data may be required if criminal charges are pursued.

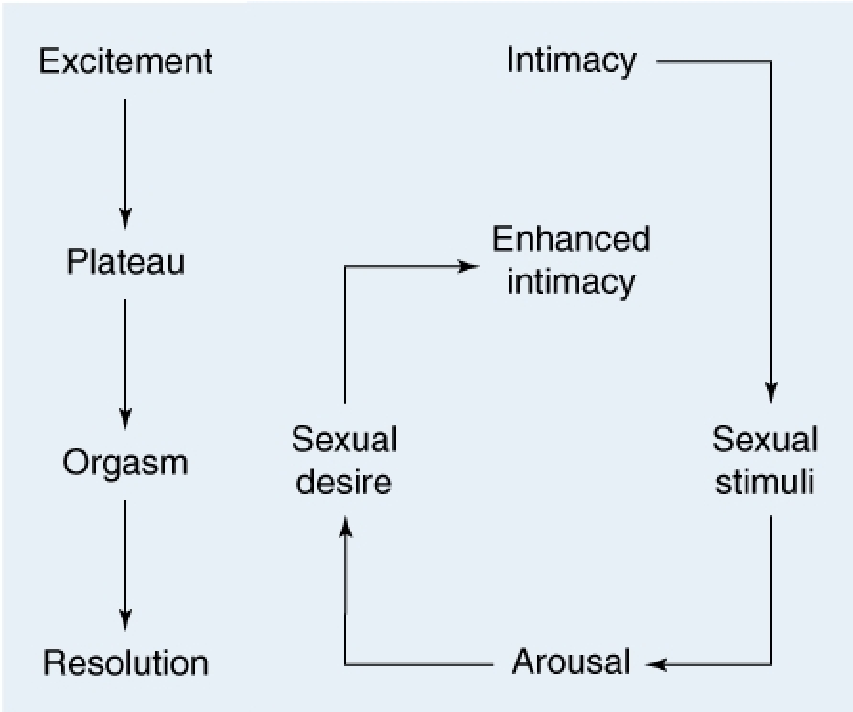
FEMALE SEXUALITY

Sexuality is one of the most complex and yet basic components of human behavior. Expressions of sexuality and intimacy remain important throughout the life span. Although basic sexual drive is biologic, its expression is determined by a variety of psychological, social, environmental, spiritual, and learned factors. Thus, sexual satisfaction is often less dependent on the physical components of sexuality than on the quality of the relationship and the context in which sexual behavior is undertaken.

Biologic Cycle

In describing the sexual response cycle, several investigators have assumed that sexual responses follow a predictable sequence of events. The number of stages within this response cycle varies, and cycles containing from two to four stages have been described (Fig. 13-2). Rather than the traditional view of the sexual response cycle progressing through discrete sequential stages of desire, arousal, orgasm, and resolution, it is now recognized that these phases overlap and that their sequence may vary (Basson, 2006).

FIGURE 13-2



Models of female sexual response. (*Adapted from Masters, 1966, and Basson, 2000, with permission.*)

Drive and Desire

The basis of desire and perceived arousal in women is poorly understood, but it appears to involve interactions among multiple neurotransmitters, sex hormones, and environmental factors. Early in the female sexual response cycle, erotic stimulation is associated with a desire, also termed *libido,* for sexual interaction. Libido varies and is considered to be the cerebral component of sexuality.

Several other factors have been closely linked to women's sexual satisfaction and libido. Based on survey data, these include stable past and current mental health, positive emotional well-being and self image, rewarding past sexual experiences, positive feelings for the partner, and positive expectations for the relationship (Bancroft, 2003; Dennerstein, 2005; Laumann, 2005).

Arousal

A woman's sexual arousal is complex and correlates positively with the sexual stimulus and its emotional context. This subconscious reflex is organized by the autonomic nervous system and processed in the limbic system in response to mental or physical stimuli that are recognized as sexual. Subjective findings of sexual arousal include vaginal and vulvar congestion, increases in vaginal lubrication, and other somatic changes such as blood pressure level, heart rate, muscle tone, respiratory rate, and temperature. However, investigators have found that in sexually healthy women, measurements of genital congestion and subjective arousal vary widely (Everaerd, 2000; Laan, 1995). There are also affective responses to sexual arousal. Feelings of joy and affirmation or feelings of fear, guilt, and awkwardness serve as cognitive feedback and modulate arousal.

CLITORAL CHANGES WITH AROUSAL

In the basal state, clitoral corporal and vaginal smooth muscles are tonically contracted. After sexual stimulation, neurogenic and endothelial release of nitric oxide (NO) leads to clitoral cavernosal artery relaxation. Arterial inflow follows, and creates increased clitoral intracavernosal pressure and clitoral engorgement (Cellek, 1998). Extrusion of the glans clitoris and enhanced sensitivity results.

VAGINAL AND VULVAR CHANGES WITH AROUSAL

In the basal state, the vaginal epithelium reabsorbs sodium from the submucosal capillary plasma transudate. However, after sexual stimulation, several neurotransmitters, including NO and vasoactive intestinal peptide (VIP), are released. These modulate vaginal vascular and nonvascular smooth muscle relaxation (Palle, 1990). Dramatic increases in submucosal capillary flow follow and overwhelm sodium reabsorption. Three to 5 mL of vaginal transudate is produced, and this enhanced lubrication is essential for pleasurable coitus. Vaginal smooth muscle relaxation increases vaginal length and luminal diameter, especially in the distal two thirds of the vagina.

Release

Masters and Johnson (1966) proposed that orgasmic release is a reflex-like response that follows once a plateau of excitement has been reached or exceeded. The physiologic and behavioral indices of orgasm involve the whole bodyâ€"facial grimaces, generalized myotonia of the muscles, carpopedal spasms, and contractions of the gluteal and abdominal muscles. For women, orgasm is also marked by rhythmic contractions of the uterus, the vaginal barrel, and the rectal sphincter, which gradually diminish in intensity, duration, and regularity following orgasm. The subjective experience of orgasm includes a feeling of intense pleasure with a peaking and rapid, exhilarating release. These sensations are reported to be singular, regardless of the manner in which orgasm is achieved (Newcomb, 1983). Women are unique in their ability to be multiorgasmic, that is, capable of a series of distinguishable orgasmic responses without a lowering of excitement between them.

Resolution

After orgasm, the anatomic and physiologic changes of excitement reverse. In women, genital vasocongestion diminishes, and the vagina shortens and narrows. A filmy sheet of perspiration covers the body, and elevated heart and respiration rates gradually return to normal. If orgasm has occurred, there is concomitant psychological and physical relaxation. If orgasm does not occur, a similar physiologic processes occurs, but at a slower rate.

Normal Variations in the Physiologic Response

Sexual function and variations in the physiologic response may be affected by many biologic and psychological aspects of reproduction and the life cycle.

PREGNANCY AND SEXUALITY

During pregnancy, sexual function may change, and a reduction in sexual desire and coital frequency is typical (Byrd, 1998). These changes may stem from fears of causing fetal harm during intercourse or orgasm. In addition, fatigue, physical discomfort, or feeling less physically attractive are other reasons.

Women who suffer recurrent miscarriage, infertility, or undergo therapeutic abortion and even those during a normal postpartum will have alterations in their physiologic and psychological sexual response. Byrd (1998) found that women who are breast feeding report less sexual activity and less satisfaction than those who were not breast feeding. The study failed to demonstrate any marked differences according to the method of delivery, although women who had cesarean delivery were more likely to resume intercourse 4 weeks postpartum than women who had delivered vaginally.

SEXUALITY DURING MENOPAUSAL TRANSITION

The baseline data from the Study of Women's Health Across the Nation (SWAN) addressed sexual behavior in 3,262 women aged 42 to 52 years who were either premenopausal or in early menopausal transition. Evidence suggests that in early menopausal transition, there were few changes in sexual practices or function (Cain, 2003)

Late in menopausal transition and with natural menopause, hormonal changes can interfere with physiologic response (Avis, 2000). Masters and Johnson (1966) described a delay in reaction time of the clitoris, delayed or absent vaginal lubrication, decreased vaginal congestion, and reduced duration of contractions with orgasm. Loss of estrogen diminishes genital blood flow, vaginal lubrication, and vaginal tissue structural integrity (Freedman, 2002; Pauls, 2005). Moreover, Sarrel (1990) correlated improved libido and orgasm with estrogen replacement in postmenopausal women. Others have shown improvement in vaginal lubrication, blood flow, and vaginal compliance in menopausal women taking systemic estrogen replacement, but these were not

correlated with subjective improvements in sexual function (Berman, 1999).

SEXUALITY IN LATE LIFE

With aging, sexuality still plays an important role in the maintenance of physical and mental health. Dennerstein (2001) suggests that even many years after menopause, an increase in desire and interest is consistently reported with a new relationship. The opportunity for sexual activity in the form of intercourse, however, is often dependent on partner issues. Both partner availability and partner health begin to shape the frequency with which this form of sexual activity occurs. Of older women, 40 to 47 percent masturbate.

In general, sexual activity declines with increasing age. Activity is reported in 30 to 78 percent of 60-year-old women, in 11 to 74 percent of those older than 70 years, and in 8 to 43 percent of 80-year-old women (Morley, 2003). Few data describe sexual function in those older than 80, but as the "Baby Boomer" cohort of a more sexually open group continues to age, the future holds promise for the desire to maintain this quality of life.

SEXUAL DISORDERS

Psychiatric sexual dysfunctions are characterized by painful intercourse or disturbances in desire, arousal, orgasm, or resolution that cause marked distress and relationship difficulty (Table 13-17). Sexual dysfunction stemming from dyspareunia may also originate from gynecologic disease and is discussed more fully in Chapters 4, Symptoms of Vulvodynia and 11, Dyspareunia.

Table 13-17 Sexual Function Disorders
Hypoactive sexual desire disorder
Persistently or recurrently deficient or absent sexual fantasies and desire for sexual activity, taking into account factors such as age and the context of the person's life
Sexual aversion disorder
Persistent or recurrent extreme aversion to and avoidance of all genital sexual conduct with a sexual partner
Female sexual arousal disorder
Persistent or recurrent inability to attain or maintain until completion of sexual activity an adequate lubrication-swelling response of sexual excitement
Dyspareunia
Recurrent or persistent genital pain associated with sexual intercourse (not caused exclusively by vaginismus or lack of lubrication)
Vaginismus
Recurrent or persistent involuntary spasm of the musculature of the lower third of the vagina that interferes with sexual intercourse
In all the above disorders
The disturbance causes marked distress or interpersonal difficulty
Sexual dysfunction is not better accounted for by another psychiatric disorder and is not due exclusively to the direct physiologic effects of a substance or a general medical condition
Types: Lifelong vs. acquired; generalized vs. situational; due to psychological factors vs. due to combined factors

Incidence

Although many studies have investigated female sexual dysfunction, prevalence rates are difficult to establish due to differing criteria and measures of sexual functioning. However, a recent literature review estimated that 64 percent of women experience low or no sexual desire, 35 percent have difficulty achieving orgasm, and 26 percent experienced sexual pain (Hayes, 2006). Most difficulties last less than 6 months, but one third may persist longer.

Risk Factors

Psychosocial risk factors for sexual dysfunction include comorbid psychological disorders, negative emotions, maladaptive cognitions (such as inaccurate expectations), cultural factors, lack of education regarding sexual functioning, couple distress, and absent physical attraction. Of these, psychiatric disorders such as depression and anxiety are frequently comorbid with sexual disorders. Thus, for most patients who suffer from sexual dysfunction, evaluations should not stop with an organic explanation (Bach, 2001).

Evaluation of Sexual Dysfunction

In accordance with the biopsychosocial approach, diagnosis of sexual disorders begins by judging if dysfunction is caused exclusively by a general medical condition, drug abuse, medication, or toxin exposure. Subsequently, evaluation for a primary psychiatric disorder should follow. Assessment typically inventories a woman's ethnic, cultural, religious, and social backgrounds and includes a frank discussion about her current sexual partner(s) and sexual expectations. Clinical judgment should take into account the patient's age and sexual experience, symptom frequency and chronicity, and determine whether a woman perceives her symptoms as distressing or impairing (American Psychiatric Association, 2000a). Importantly, a woman should be asked if the sexual difficulty has always been present or has developed only within a certain time period, and if it persists across all situations or only appears in certain circumstances. Finally, referral to a psychiatrist or psychologist may be indicated for a thorough psychiatric interview.

Treatment of Sexual Dysfunction

Multidisciplinary treatment is ideal for patients with sexual dysfunction. A team would typically include the referring physician, gynecologist, psychologist, and a nurse-specialist. In organic disorders, it may be necessary to include specialists in urology, gastroenterology, and anesthesiology. Psychological approaches usually include some combination of sexual education, communication enhancement, identification of emotional and cultural factors, cognitive-behavioral therapy, and couples therapy.

PEDIATRIC GYNECOLOGY: INTRODUCTION

Pediatric gynecology is a unique subspecialty which encompasses knowledge from various specialties including general pediatrics, gynecology, and reproductive endocrinology, as well as pediatric endocrinology and pediatric urology. Treatment of a particular patient may therefore require the collaboration of clinicians from one or more of these areas.

Gynecologic disorders in children can differ greatly from those encountered in the adult female. Even the simple physical examination of the genitalia differs significantly. A thorough understanding of such differences can aid in clarifying and diagnosing the variety of gynecologic abnormalities seen in this age group.

PHYSIOLOGIC CHANGES WITH PUBERTY

Puberty marks the normal physiologic transition from childhood to sexual and reproductive maturity. Each landmark of hormonal and anatomic change during this time represents a spectrum of what is called "normal".

With puberty, primary sexual characteristics of the hypothalamus, pituitary, and ovaries initially undergo an intricate maturation process. This maturation leads to the complex development of secondary sexual characteristics involving the breast, sexual hair, and genitalia, in addition, to a limited acceleration in growth.

Hypothalamic-Pituitary-Ovarian Axis

A carefully orchestrated cascade of events unfolds in the neuroendocrine system that regulates subsequent development of the female reproductive system (see Chap. 15, Steroidogenesis Across the Life Span).

In utero, gonadotropin-releasing hormone (GnRH) neurons develop in the olfactory placode. These neurons migrate through the forebrain to the arcuate nucleus of the hypothalamus by 11 weeks of gestation. They form axons that extend to the median eminence and to the capillary plexus of the pituitary portal system (Ronnekliev, 1990; Schwanzel, 1989; Silverman 1987). Gonadotropin-releasing hormone, a decapeptide, is influenced by higher cortical centers and is released in a pulsatile fashion into the pituitary portal plexus. As a result, the GnRH "pulse generator" stimulates secretion of gonadotropins, that is, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), from the anterior pituitary by midgestation. In turn, the pulsatile release of gonadotropins stimulates ovarian synthesis and release of gonadal steroid hormones. Concurrently, accelerated germ cell division and follicular development begins, resulting in the creation of 6 to 7 million oocytes by 5 months' gestation. By late gestation, gonadal steroids exert a negative feedback upon both the pituitary gonadotropins and hypothalamic GnRH secretion. During this time, the oocyte number decreases through a process of gene-related apoptosis to reach 1 to 2 million by birth (Fig. 14-1) (Vaskivuo, 2001).

Variation in oocyte number and hormone levels during the prenatal and postnatal periods. DHEA = dehydroepiandrosterone; FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone.

At birth, FSH and LH levels rise abruptly in response to the fall in placental estrogen, and gradually decline within the first few months of life to reach prepubertal levels by age 1 to 4 years. This transient rise in gonadotropin levels, followed by an increase in gonadal steroid levels, is thought to explain instances of neonatal breast budding and minor bleeding from endometrial shedding.

The childhood years are thus characterized by low plasma levels of FSH, LH, and estradiol. However, studies suggest that the GnRH pulse generator is exquisitely sensitive to minute amounts of gonadal steroids (Plant, 1994). True central precocious puberty may develop as a result of premature activation of the GnRH pulse generator.

During childhood, the ovary increases in size and undergoes active follicular growth and atresia. As a result of this attrition, by puberty only 300,000 to 500,000 oocytes remain (Speroff, 2004).

Pubertal Changes

Initial pubertal changes occur between the ages of 8 and 13 years in most North American females (Tanner, 1985). Changes before or after are categorized as either precocious or delayed puberty and warrant evaluation. At approximately age 10 to 12 years, breast budding, termed *thelarche,* is the first physical sign in 90 percent of girls. Alternatively in a minority, pubic hair growth, known as *pubarche* develops first. Marshall and Tanner (1969) recorded breast and pubic hair development in 192 English schoolgirls and created what we now know as the *Tanner stages* (Fig. 14-2). Following breast and pubic hair growth, adolescents, during a 3-year span from ages 10.5 to 13.5 years, undergo an accelerated increase in height, termed a *growth spurt* . The mean age of menarche in white girls is 12.7 years and 6 months earlier, or 12.1, in black girls (Tanner, 1973).

GYNECOLOGIC EXAMINATION

An adolescent who has reached the age of 18 may consent to medical examination and treatment. Prior to this age, a minor child must have the consent of a parent or legal guardian (except in emergency) for examination and treatment.

A routine yearly examination of a child by their pediatrician will generally include a brief examination of the breasts and external genitalia. If visible externally, congenital anomaliesâ€”such as imperforate hymen may be identified during this examination. Alternatively, if parent or child has a specific complaint regarding vulvovaginal pain, rash, bleeding, discharge, or lesion, a gynecologic examination is directed toward the area of concern.

Importantly, a parent or guardian should be present at the examination. This allows a child to understand that the examination is sanctioned. Moreover, clinicians can use this opportunity to inform a parent about findings and potential treatment. This may also be an opportune time to emphasize points regarding inappropriate genital touching and the importance of parental notification if this occurs. In the mid-to-late teenage years, however, an adolescent may prefer, for privacy reasons, not to be examined with a parent present.

"Child-friendly" objects in the examination room such as posters, books, toys, and pictures and distracting conversation can ease fears and significantly aid in examination of the young female (Kass-Wolff, 2003). Similarly, using an anatomically appropriate doll to explain the examination and having the child repeat the procedure on the doll may decrease anxiety.

The examination begins with a less-threatening approach of checking the ears, throat, heart, and lungs. Breasts are inspected. The external genital examination is best performed with the child in a frog-leg or knee-chest position to improve visualization. Occasionally, the patient may feel more comfortable sitting in a parent's lap. Sitting on a chair or examination table, the parent allows the child's legs to straddle the parent's thighs (Fig. 14-3).

Once the child is optimally positioned, each labia may be gently held with a thumb and forefinger and pulled toward the examiner and laterally. In this manner, the introitus, hymen, and lower portion of the vagina are inspected (Fig. 14-4). An internal examination is rarely necessary unless a foreign body, tumor, or vaginal bleeding is suspected. This evaluation is best accomplished under general anesthesia in an ambulatory care center. Vaginoscopy may be performed using a hysteroscope or cystoscope to provide illumination as well as irrigation (Baldwin, 1995; Pokorny, 1997). During vaginoscopy, normal saline is used as the distension medium. The labia majora are manually approximated to occlude the vagina and achieve distention of the vaginal canal.

PROBLEMS IN PEDIATRIC GYNECOLOGY

Labial Adhesion

Adhesion between the labia minora begins as a small posterior midline fusion, which is usually asymptomatic. This fusion may remain an isolated minor finding or may progress toward the clitoris to completely close the vaginal orifice. Also termed *labial agglutination* , this adhesion develops in 1 to 5 percent of prepubertal girls and in approximately 10 percent of female infants within the first year of life (Berenson, 1992; Christensen, 1971).

The cause of labial adhesion is unknown, although hypoestrogenism is implicated. This fusion typically develops in a low-estrogen environmentâ€”it is seen in infants and young girls, and tends to undergo spontaneous resolution at puberty (Jenkinson, 1984). Additionally, erosion of the vulvar epithelium is thought to underlie some cases of labial adhesion. For example, adhesion has been found in association with vulvar irritation such as lichen sclerosus, herpes simplex viral infections, and with vulvar trauma following sexual abuse (Berkowitz, 1987).

The diagnosis is made by visual inspection of the vulva. The labia majora appear normal, whereas the labia minora are fused with a distinct thin line of demarcation or *raphe* between them. In severe cases, agglutination leaves only a ventral pinhole meatus between the labia. Located immediately beneath the clitoris, this small opening may lead to urinary dribbling as urine pools behind the adhesion. In these cases, urinary tract infection or urethritis may develop (Fig. 14-5).

FIGURE 14-5

Labial adhesion. The labia minora are agglutinated in the midline. *(From The North American Society for Pediatric and Adolescent Gynecology, 2001, with permission.)*

The treatment of labial adhesions varies according to the degree of scarring and symptoms. In many instances, if the patient is asymptomatic, no treatment is necessary, as the adhesion will typically resolve spontaneously with the rise of estrogen levels at puberty. Extensive adhesion with urinary symptoms, however, will require treatment with an estrogen cream. Estradiol (Estrace, Warner Chilcott, Rockaway, NJ) or alternatively, conjugated equine estrogen (Premarin, Wyeth, Madison, NJ) creams may be applied to the fine, thin raphe twice daily for 2 weeks. This is followed by daily applications for an additional 2 weeks. A generous pea-sized amount of cream is placed with a finger or cotton-tipped applicator to the raphe. With each application, gentle outward traction is exerted on the labia majora to help separate the adhesion. Similarly, light pressure may also be applied with the cotton applicator itself, as tolerated. After adhesion separation, petroleum jelly (Vaseline, Unilever, Englewood Cliffs, NJ) or vitamins A and D ointment (A&D ointment, Schering-Plough HealthCare Products, Berkeley Heights, NJ) may be applied nightly for 6 months to decrease the risk of recurrence. If the adhesion reforms during the subsequent months or years, the process may be similarly repeated. Occasionally, with overuse of estrogen cream, minor breast budding may develop, at which point topical treatment is discontinued.

Manual separation of labial adhesion in an outpatient setting without analgesia is not advised, as significant pain and emotional trauma to the child may result. In addition, recurrence is much more common. However, if adhesions persist despite consistent use of estrogen cream as described above, labia minora separation may be attempted several minutes after applying 5-percent lidocaine ointment to the adhesion raphe.

If separation is not easily accomplished or tolerated by a child, then surgical separation is recommended in an operating room under general anesthesia as an outpatient procedure. Division of the fused labia, also termed *introitoplasty* , involves a midline incision, with suturing of the skin to the underlying mucosa with absorbable suture (Capraro, 1972). To prevent repeated agglutination after surgery, an estrogen cream should be applied nightly for 2 weeks, followed by an emollient cream nightly for at least 6 months.

Vulvitis

ALLERGIC, CONTACT, AND IRRITATIVE DERMATITIS

Inflammation of the vulva may develop in isolation or in association with vaginitis. In such cases, prepubertal girls may complain of vulvar discomfort, dysuria, and itching. Although the underlying pathophysiologies of allergic, contact, and irritative dermatitis vary, the clinical appearance is usually similar. In affected females, vesicles or papules form on bright red edematous skin (Fig. 14-6). In chronic cases, however, scaling, skin fissuring, and lichenification may be noted. In response, a detailed history should be directed to the level of hygiene, degree of continence, and exposure to potential skin irritants. Frequently, children may develop diaper dermatitis as a result of urine and stool exposure. Corrective measures include attempts to keep the skin dry by more frequent diaper changes or by application of emollient creams, such as Vaseline or A&D ointment, to create a barrier against moisture.

Diaper rash dermatitis and secondary candidiasis in a girl receiving antibiotic therapy. *(From Wolff, 2007, with permission.)*

Significant pruritus may develop from contact or allergic vulvitis. Typical offending agents include bubble baths and soaps, laundry detergents, fabric softeners and dryer sheets, bleach, and perfumed or colored toilet paper. Topical creams, lotions, and ointments used to soothe an area may also be an irritant to some children. For most, removing the offending agent and encouraging once- or twice-daily sitz baths is sufficient. These baths consist of placing two tablespoons of baking soda in warm water and soaking for 20

minutes. If itching is severe, an oral medication may be prescribed such as hydroxyzine hydrochloride (Atarax, Pfizer, New York, NY) 2 mg/kg/d divided in four doses, or application of a 2.5-percent topical hydrocortisone cream twice daily for 1 week.

LICHEN SCLEROSUS

Additionally, vulvitis may be caused by lichen sclerosus, which similarly to labial adhesions, can develop concurrently with hypoestrogenism or with inflammation. The pathophysiology is unknown, but development of lichen sclerosus in monozygotic twin girls suggests a genetic role (Meyrick Thomas, 1986). Patients may complain of intense itching, discomfort, bleeding, excoriations, and dysuria. The vulva displays hypopigmentation; atrophic, parchment-like skin; and occasional fissuring (see Fig. 4-1). Lesions are usually symmetrical and may form an hour-glass appearance around the vulva and perianal areas. Diagnosis typically relies on visual inspection; however, rarely a vulvar biopsy may be warranted if the classic skin changes are absent.

Treatment consists of topical corticosteroid cream such as 2.5-percent hydrocortisone, applied nightly to the vulva for 6 weeks. If improvement is noted, the dose may be lowered to 1-percent hydrocortisone and continued for 4 to 6 weeks. Thereafter, strict attention to hygiene and use of petroleum-based ointments is recommended. Severe cases will require a more potent corticosteroid such as clobetasol propionate (Temovate, GlaxoSmithKline, Philadelphia, PA), 0.05 percent applied twice daily for 2 weeks. This initial dosing is followed by an individualized regimen, which slowly tapers the dose to a once-weekly bedtime application.

INFECTION

Some common infectious organisms that may cause prepubertal vulvitis include group A β-hemolytic *Streptococcus, Candida* species, and pinworms. Group A β-hemolytic streptococci may present with a bright beefy-red vulva and introitus. A child may have symptoms of dysuria, vulvar pain, pruritus, or bleeding. In most cases, vulvovaginal culture and clinical examination typically lead to diagnosis. Group A β-hemolytic *Streptococcus* may be treated with a first- generation penicillin or cephalosporin or other appropriate antibiotic for 2 to 4 weeks.

Candidiasis is rarely seen in nonestrogenized prepubertal girls. It more often develops during the first year of life, after a course of antibiotics, or in females with juvenile diabetes or an immunocompromised condition. Diagnosis is assisted by visual inspection of a reddened, raised rash with well-demarcated borders and occasional satellite lesions. Microscopic examination of a vaginal sample prepared with 10-percent potassium hydroxide (KOH) will help identify hyphae (see Fig. 3-15). Treatment consists of twice-daily vulvar application of antifungal creams such as clotrimazole, miconazole, or butaconazole for 10 to 14 days or until the rash is cleared.

Enterobius vermicularis , also known as the *pinworm* , can be a source of intense vulvar itching, particularly at night. Nocturnal pruritus results from an intestinal infection with these 1-cm long, threadlike white worms that often exit the anus at night (Pierce, 1992; Zeiguer, 1993). By inspecting this area with a flashlight at night when the child is asleep, parents may identify worms exiting the anus. The Scotch-tape test entails pressing a piece of tape to the perianal area in the morning, affixing the tape to a slide, and visualizing eggs with microscopy. Treatment consists of mebendazole (Vermox, Janssen-Cilag, Titusville, NJ), 100 mg orally in a single dose and repeated after 1 week.

Physiologic Discharge

Physiologic discharge is often seen transiently in the newborn as a result of exposure to maternal estrogen in utero. This usually appears as a clear to whitish mucous discharge. Also in the first few days after birth, the endometrium may undergo transient shedding and a bloody discharge is seen.

Vulvovaginitis

Vulvovaginitis is one of the most common gynecologic problems of prepubertal girls. Three fourths of cases of vulvovaginitis in this age group are nonspecific, with culture results yielding normal flora. Alternatively, several infectious agents, discussed subsequently, may be identified.

NONSPECIFIC VULVOVAGINITIS

Several months after birth, as estrogen levels wane, the vulvovaginal epithelium becomes thin and atrophic. As a result of this change, the vulva and vagina are more susceptible to irritants and infections until puberty.

More than 50 percent of visits to the pediatric gynecologist involve vulvovaginal complaints (Emans, 1998). The pathogenesis is not well defined, but known instigating factors that can lead to nonspecific vulvovaginitis are included in Table 14-1. Symptoms include itching, vulvar redness, discharge, dysuria, and odor. Most children and adolescents who are not sexually active tolerate speculum examination poorly, but vaginal swab for bacterial culture is typically comfortably obtained. In cases of nonspecific vulvovaginitis, cultures usually only isolate normal vaginal flora. Culture results revealing bowel flora suggest contamination with fecal aerobes.

Co-existent eczema or seborrhea
Chronic disease and altered immune status
Sexual abuse

Treatment is directed toward correction of the underlying cause. Itching and inflammation may be relieved with the use of a low potency topical corticosteroid (hydrocortisone, 1 or 2.5 percent). Occasionally severe itching can lead to a secondary bacterial infection that requires treatment with an antibiotic. Antibiotics commonly used include amoxicillin, an amoxicillin plus clavulanic acid combination, or a similar cephalosporin, given during a 7- to 10-day course.

INFECTIOUS VULVOVAGINITIS

Infectious vulvovaginitis often presents with a malodorous, yellowish or greenish purulent discharge, and vaginal cultures are routinely obtained in these cases. The respiratory pathogen, group A β-hemolytic *Streptococcus* , is the most common specific infectious agent found in prepubertal females and is isolated from 7 to 20 percent of girls with vulvovaginitis (Pierce, 1992; Piippo, 2000). Treatment of group A β-hemolytic *Streptococcus* consists of amoxicillin, 40 mg/kg taken three times daily for 10 days. Less frequently, other respiratory pathogens found include *Haemophilus influenzae, Staphylococcus aureus* , and *Streptococcus pneumoniae* . Enteric pathogens such as *Shigella* and *Yersinia* species may also be found by culture of vaginal discharge. Classically, *Shigella* species incite a mucopurulent bloody discharge, which typically follows diarrhea caused by the same organism. Treatment is with trimethoprim-sulfamethoxazole (TMP-SMZ), 6 to 10 mg/kg/d orally, divided every 12 hours (Bogaerts, 1992).

Sexual abuse may result in infections, including those caused by *Neisseria gonorrhoeae, Chlamydia trachomatis* , herpes simplex virus (HSV), *Trichomonas vaginalis* , and human papillomavirus (HPV) (see Chap. 3). The clinical presentation of each mirrors the infectious findings in adults. Child protective services should be notified of any child found to have a sexually transmitted disease.

Genital Trauma

The prepubertal vulva is less protected from blunt injury due to the lack of labial fat pads (Fig. 14-7). In addition, children are more physically active, thereby increasing the risk of trauma. Fortunately, most injuries to the vulva are blunt, minor, and accidental. Sharp-object penetration, however, may cause more serious injury to the vulvovaginal area. Sexual or physical abuse should also be considered in many cases of genital trauma. Management of genital trauma is discussed in Chapter 4, Vulvovaginal Trauma.

Ovarian Tumors

Ovarian tumors are the most common neoplasm found in childhood (Breen, 1977). They may be found prenatally during maternal sonographic evaluation, as well as during prepubertal years and adolescence. Although most are benign, approximately 1 percent of all malignant tumors in this age group are of ovarian origin (Breen, 1977, 1981).

FETAL AND NEONATAL OVARIAN CYSTS

Most fetal and neonatal ovarian cysts are identified incidentally during antepartum maternal sonographic examination. Although the true incidence of fetal ovarian cysts is not known, some cystic development has been reported in 30 to 70 percent of fetuses (Brandt 1991; Lindeque, 1988). Most fetal and neonatal cysts result from maternal hormonal stimulation in utero. They are typically unilateral, asymptomatic, and tend to regress spontaneously by 4 months of age, whether they are simple or complex. The risk of malignancy in fetal and neonatal ovarian cysts is low, although rupture, intracystic hemorrhage, visceral compression, and torsion followed by autoamputation of the ovary or adnexa may be seen.

For uncomplicated fetal or neonatal cysts measuring less than 5 cm in diameter, the management is observation and sonographic examination every 4 to 6 weeks (Bagolan, 2002; Murrray, 1995; Nussbaum, 1988; Spence 1992). For simple cysts measuring greater than 5 cm, percutaneous cyst aspiration may be considered to prevent torsion (Bryant, 2004; Salkala, 1991). Large complex ovarian cysts that do not regress require surgical excision.

PREPUBERTAL OVARIAN CYSTS

Ovarian cysts may develop during the neonatal period and infancy. These result from the postnatal gonadotropic surge seen with the withdrawal of maternal hormones after birth. Most cysts are simple, asymptomatic, and tend to regress within several months. However, ovarian neoplasms found in childhood are most often germ cell tumors (see Chap. 36) (Lack, 1984).

Presenting symptoms in children with ovarian cysts are varied. Asymptomatic cysts may be discovered incidentally during abdominal examination or during sonographic examination for some other indication. Enlarging cysts may cause increased abdominal girth or chronic pain. Hormone-secreting cysts may lead to isosexual or heterosexual precocious puberty. Moreover, rupture, hemorrhage, or torsion may precipitate acute abdominal pain, similar to that seen in adults.

In the older adolescent and adult, transvaginal sonography is the preferred tool to diagnose ovarian tumors. However, a prepubertal child will not tolerate examination with a transvaginal probe. Therefore in this age group, transabdominal pelvic sonography is most frequently used. Computed tomography is helpful if a mature cystic teratoma (dermoid cyst) is suspected, as fat is better appreciated with this modality. Although magnetic resonance (MR) imaging is preferred for evaluation of congenital mÃ¼llerian anomalies, it is less helpful than pelvic sonography for ovarian mass determination.

As with those of the fetal and neonatal periods, small simple ovarian cysts without septation or internal echoes may be monitored with serial sonographic examination. Most less than 5 cm in size will resolve within 1 to 4 months (Thind, 1989). Persistent or enlarging cysts warrant surgical intervention, and laparoscopy is the preferred method. Optimal management includes fertility-sparing ovarian cystectomy with preservation of any normal ovarian tissue.

Breast Development and Disease

At puberty, under the influence of ovarian hormones, the breast bud grows rapidly. The epithelial sprouts of the mammary gland branch further and become separated by increasing deposition of fat.

Newborns may have some minor breast budding due to transplacental passage of maternal hormones in utero. Similarly, newborn breasts may produce *witches' milk* , which is a bilateral white nipple discharge, also as a result of maternal hormone stimulation. Both effects are transient and most often diminish during several weeks to months.

Breast development, termed *thelarche* , begins in most girls between the ages of 8 and 13 years. Thelarche prior to age 8 or lack of breast development by age 13 is considered abnormal and should be investigated.

BREAST EXAMINATION

A breast evaluation and examination begins in the newborn period and extends through the prepubertal and adolescent years, as abnormalities can develop in any age group. Assessment includes inspection for accessory nipples, infection, lipoma, fibroadenoma, and premature thelarche.

POLYTHELIA

Accessory nipples, also termed *polythelia* , is common and noted in 1 percent of patients. Most frequently, a small areola and nipple are found along the embryonic milk line, which extends from the axilla to the groin (Latham, 2006; Loukas, 2007).

Accessory nipples are usually asymptomatic, and excision is not required. Rarely, however, they may contain glandular tissue, which can lead to pain, nipple discharge, or development of fibroadenomas (Aughsteen, 2000; Oshida 2003).

PREMATURE THELARCHE

Thelarche may begin before the age of 8 years in some girls and is most commonly seen in girls aged less than 2 years (Fig. 14-8). This early breast maturation is termed *premature thelarche* . It differs from precocious puberty in that it is benign, self-limited, and develops in isolation, without other signs of pubertal development. Premature thelarche is suspected if a girl's height falls within established percentile curves and minimal breast tissue growth or nipple maturation is noted during surveillance. Monitoring body growth and breast changes alone may suffice, but in those with increased height or weight or with other pubertal changes, additional testing for precocious puberty is warranted. Accordingly, analysis of a girl's growth curve and Tanner stage, radiographic bone age study, and gonadotropin measurement may each be indicated. Bone age can be determined at many skeletal sites, and

the left hand and wrist are by far the most commonly used. Premature thelarche is suggested if the bone age falls within 1 year of chronologic age (normal). However, if the bone age is advanced by 2 or more years, puberty has begun and evaluation of precocious puberty is warranted. Serum estradiol levels may be slightly elevated in girls with premature thelarche and are seen more commonly in very-low-birth-weight infants (Escobar, 1976; Ilicki, 1984; Klein 1999; Nelson 1983). In most cases, premature breast development regresses or stabilizes, and treatment consists of reassurance with careful surveillance for other signs of precocious puberty.

BREAST ASYMMETRY

Asymmetrical breast growth may be seen commonly during early breast development stages in adolescent girls aged 13 to 14 years. A thorough examination should be performed to check for the presence of a breast mass such as a fibroadenoma, cyst, or infection. If no such pathologic process exists, yearly examinations are performed to determine the extent of asymmetry.

The etiology of breast asymmetry is not known, although there have been cases of sports injuries or surgical trauma occurring during early breast development that may have led to unequal growth (Goyal, 2003; Jansen, 2002). Moreover, a strong association of asymmetry and tuberous breast formation has been noted (DeLuca-Pytell, 2005).

In most cases, asymmetry will resolve by completion of breast maturity (Templeman, 2000). Therefore, a decision about surgical intervention involving augmentation or reduction mammoplasty is not made until full breast growth is attained. Until that time, adolescents may be fitted with padded bras or even prosthetic inserts to ensure symmetry when fully clothed. Although most

adolescents with minor breast asymmetry choose not to undergo surgical intervention, others may elect to visit with a plastic surgeon to discuss options, particularly if asymmetry is pronounced.

BREAST HYPERTROPHY

Rarely, adolescents develop extremely large breasts without concurrent large breast masses. Breast hypertrophy can be symptomatic and complaints may include back pain, shoulder discomfort from bra-strap pressure, and kyphosis, not to mention the social stigmata that can cause psychological distress. These young women will often seek reduction mammoplasty, but surgery should be delayed until breast growth is completed, as determined by serial breast measurements, typically between the ages of 15 to 18 years.

TUBEROUS BREASTS

With normal breast development, ventral growth projects the areola forward and peripheral growth enlarges the breast base. In some adolescents, the fascia is densely adhered to the underlying muscle and fails to be separated from its muscular layer by laterally expanding breast tissue (Fig. 14-9). This restricts peripheral expansion of the breast base, and breast growth is directed forward. Termed *tuberous breasts* , these breasts display a tubular appearance that is characterized by a narrowed breast base, elevation of the skin fold under the breast, and hypoplastic development of the lower portion of the breast. To optimize surgical correction of this deformity, Grolleau and colleagues (1999) developed a classification system based on the number of breast quadrants involved. Type I defects involve only the medial lower breast quadrant; type II, both lower quadrants; and type III, all quadrants.

FIGURE 14-9

Comparison of normal and tuberous breast development. *(Redrawn from Grolleau, 1999, with permission.)*

Additionally, this type of appearance can result from exogenous hormone replacement. This is often given to girls who lack breast development due to genetic, metabolic, or endocrine conditions. To avoid tuberous development in this setting, hormone replacement is initiated at small dosages and gradually increased over time. For example, conjugated equine estrogen (Premarin), 0.3 mg may be given orally each day for 6 months, followed by incremental dose increases every 6 months, through doses 0.625 mg and 0.9 mg, to finally reach 1.25 mg daily. Medroxyprogesterone acetate (Provera, Pfizer, New York, NY), 10 mg is given orally each day for 12 days of the month to prompt withdrawal menses. Once estrogen dosing has reached 1.25 mg daily, the patient may alternatively be placed on a low-dose oral contraceptive pill.

LACK OF BREAST DEVELOPMENT

Congenital absence of breast glandular tissue, termed *amastia,* is rare. More commonly, a lack of breast development results from low estrogen levels caused by constitutionally delayed puberty, debilitating chronic disease, radiation or chemotherapy, genetic disorders such as gonadal dysgenesis, or extremes of physical activity such as ballet or endurance sports. Treatment is based on etiology. For example, once a competitive athlete completes her career, breast development may begin spontaneously without hormonal treatment. Alternatively, to prompt breast development and prevent osteoporosis, adolescent girls with gonadal dysgenesis will require some form of hormonal replacement, such as that described earlier for the prevention of tuberous breasts.

NIPPLE DISCHARGE

Nipple discharge may present in varied colors, which may indicate their etiology. For example, milky white discharge typifies galactorrhea; cloudy yellow or light-green liquid may indicate infection; and greenish-brown discharge is commonly associated with ductal ectasia. Serosanguinous nipple fluid may reflect an intraductal papilloma or rarely cancer. In general, the pathophysiology and management of these discharges mirrors that of an adult female (see Fig. 12-6).

BREAST CYSTS

When an adolescent complains of a breast lump, often the findings are consistent with fibrocystic changes. These are characterized by patchy or diffuse, band-like thickenings or lumps. As many as 50 percent of women are found to have fibrocystic changes on clinical examination, and the etiology is unknown (Love, 1982).

Sonography may aid in distinguishing between a cystic and solid mass and defining cyst qualities (Garcia, 2000). In contrast, mammography has a limited role in the evaluation of child and adolescent breast tissue. Mammography has limited sensitivity and specificity in young developing breasts, and the dense nature of their breast tissue yields high rates of false-negative results (Williams, 1986).

Actual breast cysts are found on occasion and will usually resolve spontaneously during a few weeks to months. If a cyst is large, persistent, and symptomatic, then fine-needle aspiration may be performed using local anesthesia in an office setting.

BREAST MASSES

Most breast masses in children and adolescents are benign and may include normal but asymmetric breast bud development, fibroadenoma, fibrocyst, lymph node, and abscess. The most common breast mass identified in adolescence is the fibroadenoma, which accounts for 68 to 94 percent of all masses (Daniel, 1968; Goldstein, 1982). Fortunately, breast cancer in pediatric populations is rare, and Neinstein (1994) cited an incidence of cancer in less than 1 percent of breast masses identified in this group. However, primary breast cancer may develop more frequently in pediatric patients with a history of prior radiation, especially to the chest wall. Additionally, metastatic disease should be considered in those with a history of malignancy.

Following identification of a breast mass on physical examination in a young female, sonography is the primary imaging method. Magnetic resonance (MR) imaging is not routinely recommended because of its high cost and limited availability.

Treatment of breast masses includes observation, needle aspiration, and surgical excision. Observation may be appropriate for small asymptomatic lesions considered to be fibroadenomas. Alternatively, in many cases, a tissue diagnosis with a minimally invasive procedure such as fine-needle aspiration is warranted. Additionally, core-needle biopsy with sonographic guidance is another percutaneous option. In any mass not surgically excised, clinical surveillance is recommended to ensure stability of the

mass (Weinstein, 2003). Masses that are symptomatic, large, or enlarging are preferably excised using local or general anesthesia in an ambulatory surgical center.

Mastitis is rare in the pediatric population, and its incidence displays a bimodal distribution. Most mastitis is seen in the neonatal period and to a lesser degree in children older than 10 years. The etiology in these cases is unclear, but the association with breast enlargement during these two periods has been implicated. *Staphylococcus aureus* is the most common isolate, and abscess develops more commonly than in the adult (Faden, 2005). Alternatively in adolescents, infections may be associated with lactation and pregnancy, trauma related to sexual foreplay, shaving periareolar hair, and nipple piercing (Templeman, 2000; Tweeten, 1998). Infections are treated with antibiotics and occasional drainage, if an abscess has formed.

Vaginal Bleeding

Neonates may present with vaginal bleeding during the first week of life due to withdrawal of maternal estrogen at birth. Bleeding typically resolves after a few days. Prepubertal bleeding in a child, however, warrants careful evaluation (Table 14-2).

Precocious Puberty

Early pubertal development may be seen in both sexes, but females are more commonly affected, with a gender ratio of 23:1 (Bridges, 1994). For girls, precocious puberty has historically been defined as the development of breast or pubic hair in girls younger than 8 years. However, Herman-Giddens and colleagues (1997) noted that girls in the United States are undergoing pubertal development at younger ages than previously reported. In black girls, puberty begins even earlier. Accordingly, to limit the proportion of girls requiring evaluation for precocious puberty, these investigators and a subsequent pediatric endocrinology task force have suggested modifying the age for evaluation of precocious puberty to younger than age 7 years for white girls and age 6 for black girls who display signs of pubertal development (Herman-Giddens 1997; Kaplowitz, 1999).

Premature pubertal development may result from a variety of etiologies. These causes have been categorized based on the site of pathogenesis and include central precocious puberty, peripheral precocious puberty, heterosexual precocious puberty, and variations of normal puberty. Most girls evaluated for precocious puberty are found to have normal pubertal development that has merely begun prior to standard temporal milestones and does not stem from underlying pathology. However, because many of the underlying etiologies of precocious puberty carry significant sequelae, girls with early pubertal development should be fully evaluated when identified.

CENTRAL PRECOCIOUS PUBERTY (GONADOTROPIN-DEPENDENT)

Early activation of the hypothalamic-pituitary-ovarian axis leads to GnRH secretion, increased gonadotropin formation, and in turn

increased gonadal sex steroid levels. Often termed *true precocious puberty* , central precocious puberty is rare and affects one in 5,000 to 10,000 individuals in the general population (Partsch, 2002). The most common cause of central precocious puberty is idiopathic, however, central nervous systems lesions must be excluded (Table 14-3).

Symptoms of central precocious puberty are similar to those of normal puberty, with breast development, growth spurt, and eventual menses. However, these are seen at an earlier age (Fig. 14-10). As outlined in Table 14-4, testing includes a left hand and wrist bone age radiographic measurement. Advanced skeletal maturation is seen in affected girls. Serum FSH, LH, and estradiol levels typically fall in the pubertal range. Early in the process, however, FSH and LH may only be elevated in the evenings, and a GnRH stimulation test can be helpful. During GnRH stimulation, GnRH (3.5 μg/kg, not to exceed 100 μg) is infused intravenously, and gonadotropins levels are measured before and at sequential intervals after infusion. Central precocious puberty is confirmed by a rise in serum LH levels following infusion. In contrast, lack of LH and FSH level elevation after infusing GnRH suggests peripheral precocious puberty. Computed tomography and MR imaging of the central nervous system may identify a cerebral abnormality.

Treatment goals focus on preventing reduced final adult height and limiting the psychological effects of early pubertal development. Epiphyseal fusion is an estrogen-dependent process. Accordingly, girls with precocious puberty are at risk for early growth plate closure and short stature in adulthood. Treatment consists of a GnRH agonist, which serves to downregulate pituitary gonadotrophs and inhibit FSH and LH release. Estrogen levels drop, and often there is a marked regression of breast and uterine size. If therapy is instituted after menses have begun, they will cease.

Typically, GnRH agonists, such as depot leuprolide acetate (Lupron Depot-PED, TAP Pharmaceuticals, Lake Forest, IL) are administered as intramuscular injection. However, data from a recent phase III trial show, histrelin, a yearly subdermal implant, is effective in sex steroid suppression in girls with central precocious puberty (Eugster, 2007).

PERIPHERAL PRECOCIOUS PUBERTY (GONADOTROPIN-INDEPENDENT)

Less commonly, elevated estrogen levels may originate from a peripheral source such as an ovarian cyst. Termed *peripheral precocious puberty* , this category is characterized by lack of GnRH pulsatile release, low levels of pituitary gonadotropins, yet increased serum estrogen levels.

Although the originating source is variable, the most common cause is granulosa cell tumor, accounting for more than 60 percent of cases (see Chap. 36, Juvenile Granulosa Cell Tumors) (Emans, 1998). Other types of ovarian cysts, adrenal disorders, iatrogenic disorders, and primary hypothyroidism are additional causes (see Table 14-3). McCune-Albright syndrome is characterized by polyostotic fibrous dysplasia, irregular cafÃ©-au-lait spots, and endocrinopathies. Precocious puberty is a frequent finding and results from estrogen production in the ovarian cysts that are common in these girls.

In girls with peripheral precocious puberty, estrogen levels are characteristically elevated, whereas serum levels of LH and FSH are low. Bone age determination shows advanced aging and GnRH stimulation shows no elevation in serum LH levels.

Treatment of peripheral precocious puberty consists of eliminating the estrogen. For those with exogenous exposure, elimination of the estrogen source, such as hormonal pills or creams, is sufficient. An estrogen-secreting ovarian or adrenal tumor will require surgical excision, and hypothyroidism is treated with thyroid hormone replacement. Some success has been found in treating patients with McCune-Albright syndrome with an aromatase inhibitor such as testolactone and letrozole (Feuillan, 1986, 2007).

HETEROSEXUAL PRECOCIOUS PUBERTY

Androgen excess with signs of virilization is rare in childhood (see Chap. 17). Termed *heterosexual precocious puberty* , this condition is most commonly caused by increased androgen secretion from the adrenal gland or ovary. Causes include androgen-secreting ovarian or adrenal tumors, congenital adrenal hyperplasia, Cushing syndrome, and exposure to exogenous androgens. Treatment is directed at correction of the underlying etiology.

VARIATIONS OF NORMAL PUBERTY

Although standardized age guidelines accurately reflect the timing of pubertal development in most girls, others begin development early. Premature thelarche, premature adrenarche, and premature menarche describe the premature pubertal development of breast tissue, pubic hair, and menses, respectively. Each develops in isolation and without other evidence of other pubertal development.

Early breast development without any other signs of puberty is termed *premature thelarche* . Assessment of precocious puberty in these girls reveals bone ages consistent with chronological age. In addition, normal FSH, LH, and estradiol levels, pelvic sonographic examinations, and growth are noted. Treatment consists of careful surveillance and reassurance that the remainder of pubertal development will progress at a normal age.

Adrenarche is the onset of dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS) production from the adrenal zona reticularis, which can be detected at around 6 years. The phenotypic result of adrenarche is development of axillary and pubic hair, termed *pubarche,* which occurs in girls at about age 8 years (Auchus, 2004). *Premature adrenarche* is defined, therefore, as the presence of pubic hair prior to age 8 without evidence of any other signs of estrogenization or virilization. Most girls will have an increased level of DHEAS, which suggests that the adrenal gland is undergoing a premature maturation (Korth-Schutz, 1976). Some girls with premature adrenarche are found to develop polycystic ovarian syndrome in adolescence (Ibanez, 1993; Miller, 1996; Rosenfield, 2007; Siklar, 2007). Others are found to have a partial deficiency of 21-hydroxylase. Therefore, girls presenting with premature adrenarche should be screened with a bone age radiograph, a serum DHEAS level, and an early morning serum 17-hydroxyprogesterone level. Treatment includes reassurance and monitoring at 3- to 6-month intervals for other signs of puberty.

Uterine bleeding that occurs once for several days or monthly, without the presence of other signs of puberty, is termed *premature menarche* . This condition is rare, and other sources of bleeding should be considered and excluded first.

Delayed Puberty

Puberty is considered delayed if no secondary sexual characteristics are noted by age 13, which is more than two standard deviations from the mean age, or if menses are still absent by age 15 (Table 14-5). Delayed puberty affects 3 percent of

adolescents and causes include chronic anovulation, constitutional delay, anatomic abnormalities, hypergonadotropic hypogonadism, and hypogonadotropic hypogonadism (see Chaps. 18 and 16, Classification System) (Albanese, 1995; Ghali, 1994; Malasanoa, 1997). Of these, constitutional delay is the most common (Albanese 1995; Ghali 1994; Layman, 1994). These adolescents present with lack of both secondary sexual characteristics and pubertal growth spurt by age 13 years. The probable cause is a delay in the reactivation of the GnRH pulse generator (Layman, 1994). Patients may be started on low-dose estrogen until puberty progresses, at which point estrogen may be discontinued. During low-dose estrogen treatment, it is not necessary to introduce progesterone withdrawal because in early puberty there is a similarly long period of unopposed estrogen prior to ovulatory cycles.

Sexuality

GENDER IDENTITY

Many couples choose to learn the gender of their baby before delivery, and with highly sensitive sonographic examination, the sex of the baby may be identified with high accuracy as early as 12 to 14 weeks' gestation. Other couples choose to learn the gender of their baby at birth.

Typically, girls are "raised as girls" and boys are "raised as boys". Gender-appropriate clothes and behaviors, as prescribed by the local community, are adopted by the child and reinforced by parental approval. Behaviors in conflict with assigned gender are generally discouraged. However, young children will often explore a variety of behaviors, both masculine and feminine, which are included in the variety of normal experiences in the process of sex-role socialization (Maccoby, 1974; Mischel, 1970; Serbin, 1980).

The task of determining sexual assignment becomes more challenging in cases of ambiguous genitalia in the newborn. Initially, the possibility of life-threatening disease, such as congenital adrenal hyperplasia, should be investigated (see Chap. 18, Congenital Ambiguity of the Genital Tract). Gender assignment may be difficult in many cases of ambiguous genitalia, and is best not performed in the delivery room, but within a few days to weeks, when tests can then identify the problem and a decision can be made.

The final gender assignment in such cases is termed the *sex of rearing,* and reflects the pattern of gender behavior to be emphasized. The final determination of the sex of rearing is based not only on the individual's karyotype, but also on the functional capacity of the external genitalia. For example, boys born with congenital absence of the penis, a rare disorder, are usually raised as females after bilateral orchidectomy and reconstruction of the scrotum to have the appearance of labia. If parental attitudes towards the assigned gender are consistent, most children assume the sex of rearing easily, regardless of their genotype.

ADOLESCENT PERCEPTIONS OF SEXUAL ACTIVITY

Adolescent sexuality develops during a period of rapid change that provides opportunities for adolescents to experience both risk-taking and health-promoting behaviors. Data from the 1995 National Survey of Family Growth reveal that the percentage of teenagers who become sexually active increases steadily after age 13 (Table 14-6) (Abma, 2001).

Research suggests that adolescents view health care providers as an important resource for information and education regarding healthy sexual development. However, many parents and educators oppose sexuality education. Concerns that providing such information will encourage the onset of intercourse, termed *coitarche* , and will increase the frequency of intercourse are typical. On the contrary, several studies have found that such education will actually delay the onset and frequency of sexual activity, increase contraceptive use, and reduce rates of unprotected intercourse (Kirby, 1999, 2001). A national survey in 1999 noted that 75 percent of adolescents attending grades 7 through 12 in public secondary schools reported that they received classes in sexuality education (Hoff, 2000). A large percentage wanted more information on specific topics such as contraception and sexually transmitted diseases (STDs) (46 percent), condom use (30 percent), emotional issues (46 percent), and testing for STDs (51 percent).

Oral sex is now more commonplace among adolescents. The National Survey of Family Growth in 2005 reported that one in four adolescents aged 15 to 19 years who had not had sexual intercourse reported practicing oral sex with a partner. Of those adolescents who practiced sexual intercourse, 83 percent of females and 88 percent of males stated they had engaged in oral sex (Mosher, 2005). Adolescents may see oral sex as an alternative way to maintain their "technical virginity", prevent pregnancy, avoid STDs, or perceive it as a step on the way to engaging in sexual intercourse with a dating partner.

Sexual activity and partner violence appear to have a frequent association in adolescent populations (see Chap. 13, Risk Factors Associated with Domestic Violence). For example, Kaestle and Halpern (2005) noted that violent victimization was more likely to occur in romantic relationships that included sexual intercourse (37 percent) compared with those that did not (19 percent). Abma and colleagues (1997) reported that among sexually active girls aged 15 to 19 years, 25 percent were forced to have nonconsensual intercourse.

CONTRACEPTION

Despite the availability of a wide range of contraceptive options, the United States has 3 million unplanned pregnancies each year, which is one of the highest rates in the industrialized world (Henshaw, 1998). Approximately 1 million of these unintended

pregnancies occur in women using oral contraceptive pills (Piccinino, 1998). Recent trends in contraceptive technology include development of equally effective methods that enhance patient compliance. These new methods include the contraceptive patch, vaginal ring, levonorgesterel-containing intrauterine system, extended-use oral contraceptive pills, and subdermal etonogestrel releasing implant (see Chap. 5, Transdermal Administration). The most commonly used contraceptive by adolescents is the combination oral contraceptive (COC) pill. A survey from the Centers for Disease Control and Prevention in 2002 revealed that of those using birth control, 44 percent used COC pills, 38 percent condoms, 10 percent injectables, and 3 percent implants (Centers for Disease Control and Prevention, 2005).

The role of the clinician caring for sexually active adolescents is twofold: to encourage prevention of unintended pregnancy and to protect against STDs. Ideally, counseling should begin prior to the onset of sexual activity, as approximately one third of adolescents do not use contraception with the first act of intercourse (Committee on Adolescents, 1999). Accordingly, this discussion should include education on the use of emergency contraception (Chap. 5, Emergency Contraception).

Adolescents commonly express concerns about contraceptive services, and these include necessity of a concurrent pelvic examination, short- and long-term contraceptive side effects, and confidentiality. Adolescents should be informed that a pelvic examination is not necessary when a contraceptive is prescribed. Pap smear screening is recommended, however, to begin 3 years after coitarche (see Table 29-3).

Many adolescents hold misperceptions about contraception including beliefs that it may cause infertility or birth defects (Clark, 2001). One survey by the Kaiser Family Foundation revealed that more than 25 percent of adolescents were not aware that oral contraceptives did not protect against STDs.

The Supreme Court has ruled that minors have the right to the availability of contraceptives (Carry v. Population Services International, 431 U.S. 678, 1977). Moreover, current law dictates that all states provide consent to adolescents for treatment of "medically emancipated" conditions such as contraception, STDs, pregnancy, substance abuse, and mental health. These are legally designated medical situations for which an adolescent may receive care without the permission or knowledge of a parent or legal guardian (Akinbami, 2003).

REPRODUCTIVE ENDOCRINOLOGY: INTRODUCTION

Normal reproductive function requires precise quantitative and temporal regulation of the hypothalamic-pituitary-ovarian axis (Fig. 15-1). Within the hypothalamus, specific nuclei release gonadotropin-releasing hormone (GnRH) in pulses. This decapeptide binds to surface receptors on the gonadotrope subpopulation of the anterior pituitary gland. In response, gonadotropes secrete glycoprotein gonadotropins, that is, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), into the peripheral circulation. Within the ovary, LH and FSH bind to theca and granulosa cells to stimulate folliculogenesis as well as ovarian production of an array of steroid hormones (estrogens, progesterone, and androgens), gonadal peptides (activin, inhibin, and follistatin), and growth factors. Among other functions, these ovarian-derived factors feedback to the hypothalamus and pituitary gland to inhibit or, at the midcycle surge, augment GnRH and gonadotropin secretion. The ovarian steroids are also critical for preparing the endometrium for implantation of the embryo if pregnancy ensues.

FIGURE 15-1

Diagram depicts positive and negative feedback loops seen with the hypothalamic-pituitary-ovarian axis. Pulsatile release of gonadotropin-

releasing hormone (GnRH) leads to release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. Effects of LH and FSH result in follicle maturation, ovulation, and production of the sex steroid hormones (estrogen, progesterone, and testosterone). Rising serum levels of these hormones exert negative feedback inhibition on GnRH and gonadotropin release. Sex-steroid hormones vary in their effects on the endometrium and myometrium as discussed in the text. Inhibin, produced in the ovary, has a negative effect on gonadotropin release.

Reproductive endocrinology is the study of hormones and neuroendocrine factors that are produced by and/or affect reproductive tissues. These tissues include the hypothalamus, anterior pituitary gland, ovary, endometrium, and placenta. A hormone is classically described as a cell product that is secreted into the peripheral circulation and that exerts its effects in distant target tissues (Fig. 15-2). This is termed *endocrine secretion.* Additional forms of cell-cell communication exist and are critical for reproductive physiology. *Paracrine* communication, common within the ovary, refers to chemical signaling between neighboring cells. *Autocrine* communication occurs when a cell releases substances that influence its own function. Production of a substance within a cell that affects that cell before secretion is termed an *intracrine* effect.

FIGURE 15-2

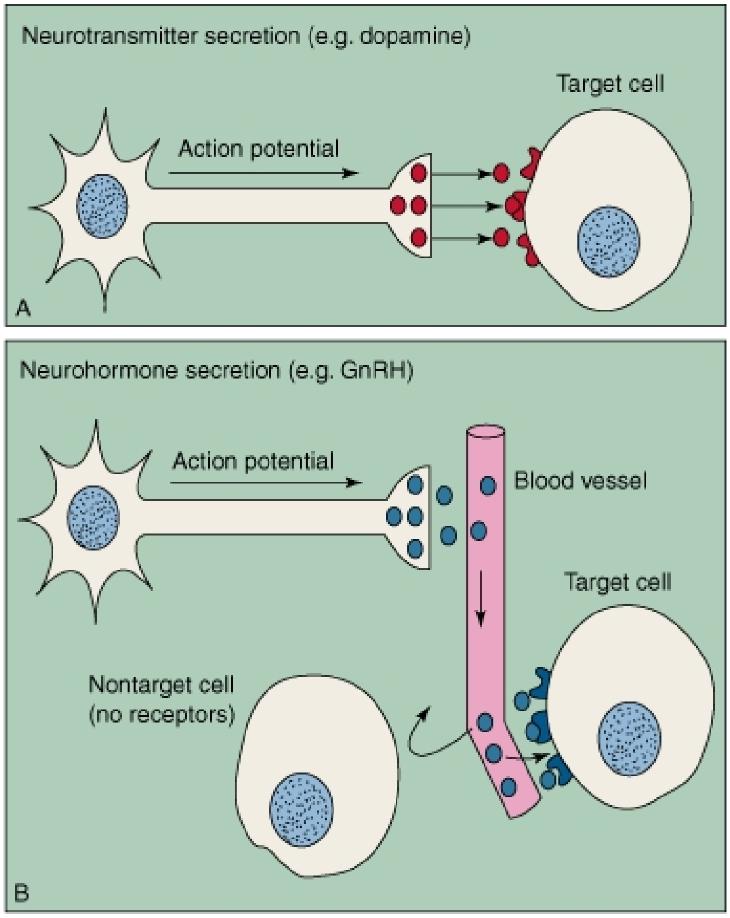
Drawing displays different types of hormone communication. **A.** Endocrine: hormones travel through the circulation to reach their target cells. **B.** Paracrine: hormones diffuse through the extracellular space to reach their target cells, which are neighboring cells. **C.** Autocrine: hormones feed back on the cell of origin, without entering the circulation.

Neurotransmitters, in classic neural pathways, cross a small extracellular space called a synaptic junction and bind to dendrites of a second neuron (Fig. 15-3). Alternatively, these factors are secreted into the vascular system. They are transported to other tissues where they exert their effects in a process termed *neuroendocrine secretion* or *neuroendocrine signaling.* An example of neuroendocrine signaling is GnRH secretion into the portal vasculature, with effects on nearby tissue. (i.e., the anterior pituitary gland).

FIGURE 15-3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Drawing illustrates types of neurotransmitter secretion. **A.** Classic neurotransmitter release and binding. Transmission of an action potential down a neural axon leads to release of neurotransmitters, which travel across a synaptic cleft to reach their target cell. **B.** Neurohormonal secretion. An action potential leads to release of neurotransmitters. In this instance, neurotransmitters enter into and travel through the circulation to reach their target organ.

REPRODUCTIVE NEUROENDOCRINOLOGY

Neurotransmitters

The list of known neurotransmitters continues to expand as our understanding of their anatomic distribution, mode of regulation, and mechanism of action increases. Neurotransmitters can be classified as: (1) biogenic amines (dopamine, epinephrine, norepinephrine, serotonin, and histamine), (2) neuropeptides, (3) acetylcholine, (4) excitatory amino neurotransmitters (glutamate, glycine, and aspartic acid), (5) the inhibitory amino acid, γ-aminobutyric acid (GABA), (6) gaseous transmitters (nitric oxide and carbon monoxide), and (7) miscellaneous factors (cytokines and growth factors).

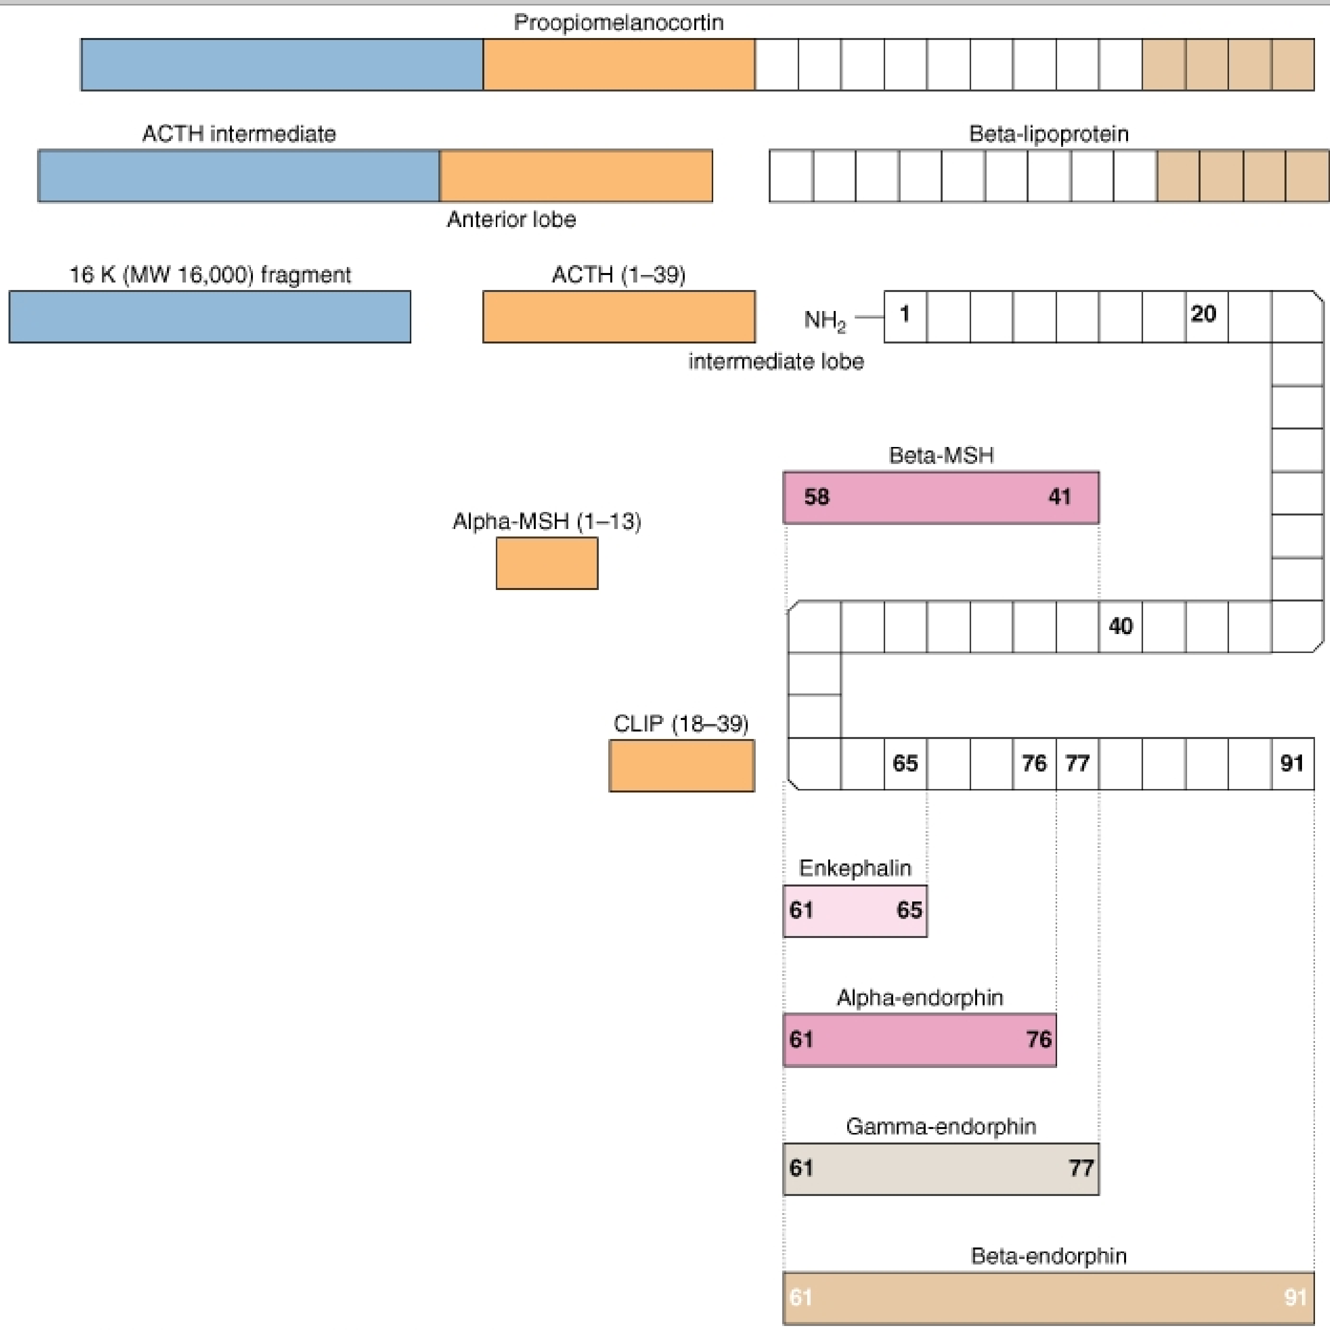
Neuropeptides in Reproduction

More than 50 neuropeptides have been described that influence behavior, pain perception, memory, appetite, thirst, temperature, homeostasis, and sleep. Clinically important neuropeptides include: the endogenous opiates, neuropeptide Y, galanin, and pituitary adenylate cyclaseâ€"activating peptide.

ENDOGENOUS OPIATES

Depending on the precursor peptide from which they are derived, these neuropeptides can be categorized into three classesâ€”endorphins, enkephalins, and dynorphins. Of these, endorphins (endogenous morphines) are cleavage products of the proopiomelanocortin (POMC) gene, which also yields adrenocorticotropin hormone (ACTH) and β-melanocyte stimulating hormone (β-MSH) (Fig. 15-4) (Howlett, 1986; Taylor, 1997). The endorphins serve a wide range of physiologic functions including the regulation of temperature, cardiovascular and respiratory systems, pain perception, mood, and reproduction.

FIGURE 15-4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Proopiomelanocortin (POMC) is a precursor polypeptide from which several biologically important peptides are derived. The site of enzymatic cleavage determines end products. First, POMC is cleaved into an adrenocorticotropin hormone (ACTH) intermediate and β-lipoprotein. The ACTH intermediate is subsequently cleaved to form the mature 39-amino-acid ACTH peptide. In contrast, β-lipoprotein is the source for β-melanocyte stimulating hormone (MSH) and the endogenous opioids, that is, enkephalin, α-endorphin, β-endorphin, and γ-endorphin.
(Redrawn from Speroff, 1999a, with permission.)

Proopiomelanocortin is produced in highest concentration in the anterior pituitary gland, but is also expressed in the brain, sympathetic nervous system, gonads, placenta, gastrointestinal tract, and lungs. The primary peptide synthesized from this pathway depends on the tissue source. For example, the predominant products in the brain are the opiates, whereas pituitary biosynthesis results principally in ACTH production.

Endogenous Opiates' Clinical Effects

Central opioidergic neurons are important mediators of the anterior and posterior pituitary gland. Administration of morphine or its analogues causes release of growth hormone (GH) and prolactin (PRL) and inhibition of gonadotropin and thyroid-stimulating hormone (TSH) release (Grossman, 1983; Houben, 1994). In addition, functional hypothalamic amenorrhea due to eating disorders, intensive exercise, and stress is correlated with an increase in endogenous opiates (see Chap. 16, Functional Disorders or Hypothalamic Amenorrhea). Elevated PRL levels also increase opioid levels in the hypothalamus. This may provide a mechanism, in addition to increased dopamine levels, for the suppression of GnRH pulsatility that occurs with hyperprolactinemia (Khoury, 1987; Petraglia, 1985).

NEUROPEPTIDE Y

The secretion and gene expression of this hypothalamic neuropeptide is highly regulated by gonadal steroids (Sahu, 1992). Neuropeptide Y (NPY) stimulates pulsatile release of GnRH and potentiates the gonadotrope response to GnRH (Pau, 1995). Negative energy balance, as seen with anorexia and bulimia, is associated with an increase in NPY levels. Therefore, it has been proposed that this neuropeptide is at least one link between nutrition and reproductive function (Kaye, 1990; McShane, 1992).

GALANIN

This 29-amino-acid neuropeptide is present in a variety of endocrine glands including the pituitary, pancreas, and adrenal medulla, suggesting that it behaves as a neurohormone. In rat models, galanin is co-expressed in GnRH-containing neurons, and females demonstrate greater levels of galanin than males (Finn, 1996). Its expression in these neurons is induced by estrogen and progesterone. Accordingly, it has been suggested that both NPY and galanin act in concert to modulate pulsatile GnRH release (Xu, 1996).

PITUITARY ADENYLATE CYCLASE-ACTIVATING PEPTIDE

Pituitary adenylate cyclaseâ€"activating peptide (PACAP) was first isolated from the hypothalamic arcuate nucleus in sheep (Anderson, 1996). As suggested by its name, PACAP binds to receptors present in the pituitary and stimulates gonadotropin secretion, albeit more weakly than GnRH. It has recently been determined that gonadotropes themselves secrete PACAP, suggesting an autocrine-paracrine role for this hormone. Of interest, PACAP gene expression is greatly increased by GnRH, functionally linking these two important reproductive peptides.

ANATOMY OF THE HYPOTHALAMUS

The hypothalamus is the source of many important neurotransmitters studied in reproductive function, and consists of nuclei located at the base of the brain, just superior to the optic chiasm. Pituitary function is primarily influenced by neurons located within the arcuate, ventromedial, dorsomedial, and paraventricular nuclei (Fig. 15-5).

FIGURE 15-5

Diagram depicts a sagittal section through the hypothalamus and pituitary gland with rostral structures to the left and caudal ones to the right. The hypothalamus is anatomically and functionally linked with the anterior pituitary by the portal system of blood supply, shown in red. The posterior pituitary consists of axon terminals of magnocellular neurons arising in the supraoptic and paraventricular nuclei of the hypothalamus. *(From Melmed, 2005, with permission.)*

Neurons within the hypothalamus form synaptic connections with other neurons throughout the central nervous system (CNS). In addition, a subset of the hypothalamic neurons project to the median eminence. In the median eminence, a dense network of capillaries arises from the superior hypophyseal arteries. These capillaries drain into portal vessels that traverse the pituitary stalk and then form a capillary network within the anterior pituitary gland (adenohypophysis). The primary direction of this hypophyseal portal system is from hypothalamus to pituitary, however, retrograde flow also exists. This creates an ultrashort feedback loop between the pituitary gland and hypothalamic neurons. The hypothalamus is thus a critical locus for integration of information from the environment, nervous system, and multiple other organ systems.

ANTERIOR PITUITARY GLAND

Initimately connected to the hypothalamus, the pituitary gland contains five hormone-producing cell types: (1) gonadotropes (which produce LH and FSH), (2) lactotropes (PRL), (3) somatotropes (GH), (4) thyrotropes (TSH), and (5) adrenocorticotropes (ACTH). Of these, gonadotropes comprise approximately 10 to 15 percent of all hormonally active cells in the anterior pituitary (Childs, 1983).

With the exception of PRL, which is under tonic inhibition, pituitary hormones are stimulated by hypothalamic neuroendocrine secretion. Although initially felt to be under separate control, it now is known that both of the gonadotropins, LH and FSH, are regulated by a single releasing peptide called gonadotropin-releasing hormone (GnRH) acting on the anterior pituitary's gonadotrope subpopulation. Most gonadotropes contain secretory granules that contain both LH and FSH, although a significant number of cells are monohormonal, that is, secrete either LH or FSH.

Of the other pituitary-releasing hormones, corticotropin-releasing hormone (CRH) stimulates biosynthesis and secretion of ACTH by the pituitary adrenocorticotropes. Thyrotropin-releasing hormone (TRH) increases secretion by the thyrotropes of thyroid-stimulating hormone (TSH), also known as *thyrotropin.* Various hypothalamic secretagogues regulate expression of somatotrope-derived growth hormone (GH). Lastly, PRL expression is primarily under inhibitory regulation by dopamine. As a consequence of these regulatory mechanisms, damage to the pituitary stalk results in hypopituitarism for LH, FSH, GH, ACTH, and TSH, but an associated increase in PRL secretion.

HYPOTHALAMIC-RELEASING PEPTIDES

These peptides have characteristics that are important for both their biologic function and clinical use. First, they are small peptides with short half-lives of a few minutes due to their rapid degradation. Secondly, hypothalamic-releasing peptides are released in minute quantities and are highly diluted in the peripheral circulation. Therefore, biologically active concentrations of these factors are locally restricted to the anterior pituitary gland. Clinically, the extremely low concentrations of these hormones render them essentially undetectable in serum. Thus, levels of their corresponding pituitary factors are measured as surrogate markers.

Gonadotropin-Releasing Hormone

Isolated in the early 1970s, GnRH is a decapeptide with a half-life of less than 10 minutes. Pharmacologic amino acid changes can markedly extend its half-life and change its biologic activity from an agonist to an antagonist (Fig. 15-6). (Redding, 1973).

Schematic drawing shows the amino acid composition of the decapeptide gonadotropin-releasing hormone (GnRH).

Most information concerning GnRH and the GnRH receptor are based on studies of a single isoform of each. Recently, however, more than one molecular form of GnRH and their receptors have been identified. With the ability to distinguish between these two receptors, it now appears that the GnRH II receptor is more widely expressed than the classic GnRH I receptor. GnRH II peptide may also have a different expression pattern than GnRH I (Neill, 2002). As a result, significant future work will be required to determine the overlapping and divergent functions of these new proteins.

MIGRATION OF THE GONADOTROPIN-RELEASING HORMONE NEURONS

Whereas other hypothalamic neurons arise within the central nervous system, GnRH-containing neurons have a unique embryologic origin. Specifically, progenitor GnRH neurons originate in the medial olfactory placode and migrate along the vomeronasal nerve into the hypothalamus. A series of soluble factors regulate GnRH neuronal migration at specific locations along their migratory route. These factors include secreted signaling molecules such as GABA, adhesion molecules, and growth factors

(Tobet, 2006; Wierman, 2004). Of these, migration is halted, at least in part, by the 154-amino-acid peptide, kisspeptin. Also known as metastin, this protein is increased at puberty and may provide a link between energy balance and the initiation of puberty.

In primates, GnRH cell bodies are primarily located within the arcuate nucleus. From these neuronal cell bodies, GnRH is axonally transported along the tuberoinfundibular tract to the median eminence. Gonadotropin-releasing hormone (GnRH) is then secreted into the portal system that drains directly to the anterior pituitary gland and stimulates gonadotropin biosynthesis and secretion. The number of GnRH neurons in the adult is strikingly low, and only a few thousand cells are dispersed within the arcuate nucleus.

The olfactory origin of GnRH neurons and nasal epithelial cells suggest a link between reproduction and olfactory signals. Compounds released by one individual that affect other members of the same species are known as *pheromones.* Pheromones obtained from the axillary secretions of women in the late follicular phase accelerate the LH surge and shorten the menstrual cycle interval of women exposed to these chemicals. Secretions from women in the luteal phase have the opposite effect. Thus, pheromones may be one mechanism by which women who are together frequently often exhibit synchronous menstrual cycles (Stern, 1998).

A subset of GnRH neurons sends projections into other areas of the central nervous system, including the limbic system. These projections are not required for gonadotropin secretion, but may play a role in modulation of reproductive behavior (Nakai, 1978; Silverman, 1987).

PULSATILE GONADOTROPIN-RELEASING HORMONE SECRETION

In elegant experiments, Ernst Knobil and colleagues demonstrated that pulsatile delivery of GnRH to the pituitary gonadotropes was required to achieve sustained gonadotropin secretion in a primate model (Knobil, 1974). As shown in Fig. 15-7, continuous infusion with GnRH rapidly decreased both LH and FSH secretion, an effect that is easily reversed with a return to pulsatile stimulation. This characteristic is exploited clinically by administration of long-acting GnRH agonists to treat steroid-dependent conditions such as endometriosis, leiomyomas, breast cancer, and prostate cancer. Such agonists disrupt pulsatile GnRH release, lead to depressed gonadotropin secretion, and in turn result in lowered serum ovarian sex steroid levels.

FIGURE 15-7

Graph shows changes in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels with variation in gonadotropin-releasing hormone (GnRH) pulsatile release. *(Redrawn from Knobil, 1980, with permission.)*

Pulsatile release of GnRH is more frequent but of lower amplitude during the follicular phase compared with that of the luteal phase. More rapid pulse frequencies preferentially stimulate LH, whereas slower frequencies favor FSH secretion (Wildt, 1981). Therefore, changes in GnRH pulse frequency affect both the absolute levels as well as the ratio of LH to FSH release.

Pulsatile activity is currently believed to be an intrinsic property of GnRH neurons. Other hormones and neurotransmitters thus

provide modulatory effects (Clayton, 1981; Yen, 1985). In animal models, estrogen increases GnRH pulse frequency, and therefore leads to an increase in LH levels relative to FSH levels. In contrast, progesterone decreases GnRH pulsatility. As less frequent GnRH pulses preferentially stimulate FSH over LH secretion, the increase in progesterone during the luteal phase may explain the preferential stimulation of FSH observed towards the end of this phase. This rise in FSH is critical for the initiation of follicular recruitment for subsequent cycles.

OPIOID PEPTIDES AND GONADOTROPIN-RELEASING HORMONE

Opioid tone in the brain plays a central role in menstrual cyclicity by suppressing the hypothalamic release of GnRH (Funabashi, 1994). Estrogen promotes endorphin secretion, and this is increased further with the addition of progesterone (Cetel, 1985). Thus, endorphin levels increase during the follicular phase, peak during the luteal phase, and drop markedly during menses. This pattern suggests that opioid tone acts along with progesterone to decrease GnRH pulse frequency in the luteal phase relative to the follicular phase. For reasons that are not fully understood, a release from opioid-suppression of GnRH occurs at the time of ovulation (King, 1984).

For many years, it was thought that GnRH neurons did not express estrogen receptors, and therefore, estrogen feedback at the hypothalamus must occur via effects on hypothalamic neurons with synaptic connections to the GnRH neurons. However, it is now known that GnRH neurons express the estrogen receptor, ER?. Progesterone receptors have not been identified in GnRH-expressing neurons. Therefore, it is currently believed that the ovarian steroids affect GnRH neuronal activity via direct and indirect mechanisms, with opioids acting as a critical intermediary for negative feedback.

OTHER HYPOTHALAMIC-PITUITARY AXES

Dopamine and Prolactin

The most important neurotransmitters in reproductive neuroendocrinology are the three monoaminesâ€”dopamine, norepinephrine, and serotonin. Dopamine-containing fibers that regulate pituitary function arise chiefly in the hypothalamic arcuate nucleus and project to the median eminence where dopamine enters the portal vessels. Dopamine present in hypophyseal-portal vessel blood is of sufficient concentration to inhibit PRL release, and dopamine is the principal prolactin inhibitory factor (PIF) (Table 15-1). In contrast, prolactin-releasing factors, although less potent, include TRH, vasopressin, vasoactive intestinal peptide (VIP), endogenous opioids, and acetylcholine.

Table 15-1 Hypothalamic-Pituitary Products and Their End Organs

Hypothalamus	Pituitary	End Organ
GnRH	LH/FSH	Gonads
Dopamine	PRL	Breast
TRH	TSH	Thyroid
CRH	ACTH	Adrenal
GHRH	GH	Somatic

ACTH = adrenocorticotropin hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormoneâ€“releasing hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; PRL = prolactin; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

There are five forms of the dopamine receptor divided into two groups, D_1 and D_2 . Cells in the anterior pituitary gland primarily express the D_2 subtypes. The medical treatment of prolactinomas has been improved in terms of both effectiveness and patient tolerance by the development of the D_2 -specific ligands. For example, the dopamine agonist cabergoline is a D_2 -specific ligand, whereas bromocriptine is nonspecific (Treatment of Pituitary Adenomas).

Thyrotropin-Releasing Hormone

As indicated by its name, thyrotropin-releasing hormone (TRH) stimulates secretion of thyroid-stimulating hormone (TSH) from the anterior pituitary gland's thyrotrope subpopulation. Of note, TRH is also a potent prolactin-releasing factor, and results in a clinical link between hypothyroidism and secondary hyperprolactinemia (see Fig. 16-5) (Krieger, 1980).

Thyroid-stimulating hormone binds to specific receptors on the plasma cell membrane of thyroid cells, stimulating the biosynthesis of thyroid hormones through an increase in thyroid gland size and vascularity. Thyroid hormone exerts negative feedback on TRH and TSH cells.

Corticotropin-Releasing Hormone

This is the primary hypothalamic factor that stimulates synthesis and secretion of ACTH. Consisting of 41 amino acid residues, corticotropin-releasing hormone (CRH) is distributed in multiple locations within the hypothalamus and other CNS areas. Corticotropin-releasing hormone release is stimulated by catecholaminergic input from other brain pathways and inhibited by endogenous opioids.

Corticotropin-releasing hormone binds to a family of CRH receptors and stimulates ACTH biosynthesis and secretion. In turn, ACTH stimulates glucocorticoid production by the adrenal's zona fasciculata and androgen production by its zona reticularis. Corticotropin-releasing hormone secretion is under negative-feedback regulation by circulating cortisol produced in the adrenal gland. In contrast, mineralocorticoid production by the zona glomerulosa is primarily regulated via the renin-angiotensin system. As a result, abnormalities in the CRH-ACTH pathway do not result in electrolyte disturbances.

Central CRH pathways are believed to mediate many stress responses (Sutton, 1982). Clinically, in women with hypothalamic amenorrhea, CRH levels have been found to be elevated. Increased levels of CRH inhibit hypothalamic GnRH secretion by direct action as well as by augmenting central opioid concentrations (see Fig. 16-5). This functional pathway may explain the association between hypercortisolism and menstrual abnormalities.

GROWTH HORMONE-RELEASING HORMONE

Growth hormone secretion by pituitary somatotropes is primarily regulated through stimulation by hypothalamic growth hormoneâ€"releasing hormone (GHRH) and inhibition by somatostatin. Expression of GHRH is limited to the hypothalamus with the exception of placental and immune cells, which also secrete this hormone. In contrast, somatostatin is widely distributed in the CNS as well as in the placenta, pancreas, and gastrointestinal tract.

As with GnRH, GHRH depends on pulsatile secretion to exert a physiologic effect. Exercise, stress, sleep, and hypoglycemia stimulate GH release, whereas free fatty acids and other factors related to adiposity blunt growth hormone release. Estrogen, testosterone, and thyroid hormone also play a role in increased GH secretion.

Growth hormone stimulates skeletal and muscle growth, regulates lipolysis, and promotes the cellular uptake of amino acids. This hormone induces insulin resistance, and therefore, GH excess may be associated with new-onset diabetes mellitus. Most of the GH's growth effects are mediated via the insulin-like growth factors, IGF-I and IGF-II. These growth factors are produced in high quantities in the liver for release into the circulation. Many of the target tissues also synthesize IGFs, where they exert local effects. Within the ovary, IGF-I modulates steroid action during folliculogenesis. This factor also suppresses GH secretion. Circulating IGF-I and IGF-II are bound to binding proteins (IGFBPs), which modulate IGF action at target tissues. In terms of mediating growth factor activity, regulating expression of these binding proteins may be as important as regulation of the IGFs themselves in modulating growth factor activity.

POSTERIOR PITUITARY GLAND

Unlike the anterior pituitary gland, the posterior pituitary (neurohypophysis) consists of the axon terminals of magnocellular neurons from the supraoptic and paraventricular nuclei of the hypothalamus (see Fig. 15-5). These neurons synthesize the nine-amino-acid cyclic peptidesâ€"oxytocin and arginine vasopressin. Precursors for these peptides are produced in the neuronal cell body and transported down the axon in secretory granules. During transport, precursors are cleaved into mature peptides and a carrier proteinâ€"neurophysin (Verbalis, 1983). Activation of these neurons generates an action potential that results in calcium influx and secretion of granule contents into the perivascular space. These secreted peptides then enter adjacent blood vessels for transport throughout the peripheral circulation.

Oxytocin

Oxytocin has significant roles in both parturition and lactation (Kiss, 2005). It is currently believed that this peptide does not play a role in spontaneous initiation of labor, as serum oxytocin levels are constant until the expulsive portion of labor (Fisher, 1983). Nevertheless, an increase in myometrial and decidual oxytocin-receptor expression has been noted near term, primarily due to an increase in estrogen levels.

It is well documented that oxytocin is the primary mediator of myometrial contractility during labor. Cervical and vaginal stimulation results in an acute release of oxytocin from the posterior pituitary in a process known as the *Ferguson reflex* . Clinically, oxytocin's ability to induce uterine contractions is exploited to induce or augment labor.

The anterior pituitary hormone, prolactin, is critical for milk production in breast alveoli. The glandular cells of the alveoli are surrounded by a mesh of myoepithelial cells. Suckling triggers nerve impulses from mechanoreceptors in the nipple and areola that increase hypothalamic neuronal activity. Axon terminals passing to the posterior pituitary gland release oxytocin, which causes the myoepithelial cells to contract and thereby express milk from the alveoli into the ducts and sinuses (Crowley, 1992b). Other conditioned stimuli, such as the sight, sound, or smell of a baby or sexual arousal, will have similar effects. Inhibition of milk let-down can follow stress, fear, embarrassment, or distraction. Therefore, women are encouraged to find a relaxing, private environment when breast feeding.

Oxytocin Expression Outside the Posterior Pituitary

Oxytocin expression has been detected in the anterior pituitary, placenta, fallopian tubes, and gonads, with high expression in the corpus luteum (Williams, 1990). Vaginal distension, such as that which occurs with coitus, also increases oxytocin release. Based on this observation, it has been suggested that oxytocin may be responsible for the rhythmic uterine and tubal contractions that aid in sperm delivery to the oocyte. Oxytocin may also play a role in orgasm and ejaculation.

CLINICAL HYPOTHALAMIC-PITUITARY AXIS ABNORMALITIES

Kallmann Syndrome

This syndrome is a developmental disorder characterized by the inability to smell (anosmia) and hypogonadotropic hypogonadism. Anosmia likely results from abnormal migration of olfactory neurons. Concurrent failure of appropriate GnRH neuronal migration leads to absent stimulation of gonadotropin biosynthesis and secretion (Crowley, 1992a). The pathophysiology and characteristics of this syndrome are further discussed in Chapter 16, Hypogonadotropic Hypogonadism.

Panhypopituitarism

This total loss of anterior pituitary function may develop following surgical or radiation treatment of pituitary adenomas. Panhypopituitarism following severe postpartum hemorrhage and the resultant hypotension is called *Sheehan syndrome.* Sheehan syndrome is relatively uncommon in industrialized nations due to resources for adequate intrapartum blood volume resuscitation. As would be expected, Sheehan syndrome is more commonly found in countries with developing health care systems. Patients exhibit characteristic clinical manifestations including failure to lactate or ovulate, loss of sexual and axillary hair, hypothyroidism, and adrenal insufficiency. Development of symptoms typically follows this order, although loss of function of the various pituitary cell types may not be complete in all women.

Hyperprolactinemia

ETIOLOGY OF HYPERPROLACTINEMIA

Elevated circulating prolactin levels can be caused by a variety of physiologic activities including pregnancy, sleep, eating, and coitus. Increased prolactin levels may also be observed following chest wall stimulation such as that which occurs with suckling, breast examination, chest wall surgery, herpes zoster infection, or nipple piercing (see Table 12-3). Prolactin is primarily regulated by tonic dopamine inhibition of secretion. Prolactin secretion is increased by serotonin, norepinephrine, opioids, estrogen, and TRH. Therefore, medications that block dopamine receptor action (phenothiazines) or deplete catecholamine levels (monoamine oxidase inhibitors [MAOIs]) may increase PRL levels (see Table 12-4). Moreover, hyperprolactinemia may be caused by tumor, radiation, or infiltrative diseases such as sarcoid and tuberculosis, which damage the pituitary stalk and prevent dopamine-mediated inhibition of PRL secretion (see Table 12-3).

Primary hypothyroidism is also associated with mild elevations in serum PRL levels (Van Gaal, 1981). Low circulating thyroid hormone levels produce a reflex increase in hypothalamic TRH levels due to loss of feedback inhibition. Thyrotropin-releasing hormone can bind directly to anterior pituitary lactotropes and stimulate PRL production (Haisenleder, 1992). As a rule, thyroid function tests should be measured when confirming a diagnosis of hyperprolactinemia, as a patient may require thyroid replacement rather than further evaluation for pituitary adenoma.

Prolactin-secreting adenomas, also termed prolactinomas, are the most common pituitary adenoma and the most common adenomas to be diagnosed by gynecologists. Most affected women present with microadenomas and signs of PRL excess such as galactorrhea and amenorrhea (Davis, 2004).

DIAGNOSIS OF HYPERPROLACTINEMIA

Serum Prolactin Levels

Hyperprolactinemia is, by definition, present in any patient with an elevated serum PRL level. Optimally, PRL levels are drawn in the morning, that is, at the time of the PRL nadir. Prior to testing, breast examination is avoided to prevent false-positive results. If a mildly elevated PRL level is found, sampling should be repeated because PRL levels vary throughout the day. Moreover, many factors including the stress of venipuncture may produce false elevations.

Normal PRL levels are typically less than 20 ng/mL in nonpregnant women, although the upper limit of normal varies by assay. Importantly, PRL levels rise nearly 10-fold during pregnancy and make detection of a prolactinoma difficult at this time. Occasionally the reported prolactin value will be falsely low due to a "hook effect" present in the assay (Frieze, 2002). That is, in the presence of very high levels of endogenous hormone, oversaturation of test antibodies prevents required competition between a patient's PRL and the labeled assay PRL. This problem is overcome with dilution of a patient's sample. Importantly, a mismatch between the adenoma size noted on magnetic resonance (MR) imaging and the degree of PRL level elevation should alert a clinician to the possibility of either an incorrect assay result or the likelihood that the macroadenoma is actually not primarily PRL secreting. Macroadenomas of any cell type may damage the pituitary stalk and prevent transfer of hypothalamic dopamine to the lactotropes.

Conversely, a patient may rarely have an elevated PRL level on assay despite a lack of clinical features of hyperprolactinemia. The hyperprolactinemia in these patients is thought to be secondary to alternate forms of PRL, including the so-called "big" or macroprolactin, which contains multimers of native PRL. Macroprolactin is not physiologically active, but may be detected by PRL assays (Fahie-Wilson, 2005).

Radiologic Imaging

Magnetic resonance imaging is advisable for all patients with confirmed hyperprolactinemia. Some experts advocate limiting imaging to women with a PRL level exceeding 100 ng/mL, as lower levels are most likely due to small microadenomas (Fig. 15-8). Although this is undoubtedly a safe approach in most women, mildly elevated PRL levels also may be due to pituitary stalk compression by a non-prolactin-secreting macroadenoma or a craniopharyngioma, which are diagnoses with potentially severe consequences.

TREATMENT OF HYPERPROLACTINEMIA

Treatment of hyperprolactinemia should begin with treatment of the underlying cause. For example, medications should be changed, if possible, or hypothyroidism should be treated. The management of pituitary adenomas includes dopamine agonists, such as bromocriptine (see Treatment of Pituitary Adenomas). Bromocriptine therapy can be reasonable instituted in a woman with a mildly elevated prolactin level and a normal pituitary on imaging. These patients can be presumed to have a small microadenoma, although the incidence of this presentation is decreasing with the advent of highly sensitive MR imaging.

Pituitary Adenomas

CLASSIFICATION OF ADENOMAS

Pituitary adenomas are the most common cause of acquired pituitary dysfunction and comprise approximately 10 percent of all intracranial tumors. Clinically, symptoms of galactorrhea, menstrual disturbances, or infertility may lead to its diagnosis. Most tumors are benign, with only an estimated 0.1 percent of adenomas developing into frank carcinoma with metastasis (Kaltsas, 2005). Nevertheless, pituitary adenomas may cause striking abnormalities in both endocrine and nervous system function (Table 15-2).

Table 15-2 Clinical Features of Pituitary Adenomas

Adenomas Cell Origin	Hormone Product	Clinical Syndrome	Reproductive Effects	Testing	Typical Results	Treatment
Lactotrope	PRL	Hypogonadism, galactorrhea	Disrupts GnRH pulsatility	Serum PRL level	Elevated	Surgical excision; dopamine agonist;see Fig. 15-10
Gonadotrope	subunits FSH, LH, subunits	Silent or hypogonadism; less commonly, gonadotropin excess or panhypopituitarism	Disrupts GnRH pulsatility	Serum gonadotropin α -subunit	Elevated	Surgical excision
Somatotrope	GH	Acromegaly/gigantism, menstrual irregularity	Disrupts GnRH pulsatility, ovarian steroidogenesis, LH receptor synthesis, and inhibin secretion	IGF-I level, 100-g glucose suppression test	Elevated No GH suppression	Surgical excision; somatostatin agonists:a octreaotide or lanreotide
Corticotrope	ACTH	Cushing syndrome, amenorrhea	Disrupts GnRH pulsatility	24-hr urine collection with free cortisol measurement	Elevated serum ACTH and urinary cortisol levels	Surgical excision; ketoconazole blunts adrenal steroidogenesis
				CRH stimulation test	Elevated serum ACTH and cortisol levels	
				BIPSS	ACTH levels in BIPSS sample higher than in serum	

Thyrotrope	TSH	Thyrotoxicosis, menstrual abnormalities	Increases SHBG; Increases conversion of androgens to estrogens	Serum TSH, T_3, and T_4 levels	All elevated	Surgical excision, PTU or tapazole preoperatively to normalize thyroid levels, β-blockers to control associated tachycardia

ACTH = adrenocorticotropin hormone; BIPSS = bilateral inferior petrosal sinus sampling; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GnRH = gonadotropin-releasing hormone; IGF = insulin-like growth factor; LH = luteinizing hormone; PRL = prolactin; PTU = propylthiouracil; SHBG = sex-hormone binding globulin; TSH = thyroid-stimulating hormone. T_3 = triiodothyronine; T_4 = thyroxine.

Pituitary adenomas were historically classified as eosinophilic, basophilic, or chromophobic, according to their hematoxylin and eosin staining characteristics. Tumors are now classified by their hormonal expression pattern as determined by immunohistochemistry (Fig. 15-9). Adenomas are further grouped by size into microadenomas (<10 mm in diameter) and macroadenomas (>10 mm in diameter).

The dot-like pattern is characteristic of many prolactin-producing adenomas. (HRP/DAB, 100x). *(Courtesy of Dr. Jack Raisanen.)*

Most adenomas secrete PRL, however, adenomas may secrete any of the pituitary hormones either as a single hormone (monohormonal adenoma) or in combinations (multihormonal adenoma). In the past, a subset of tumors was considered nonsecreting. However, with more sensitive assays, most have been determined to secrete the common α-subunit or the gonadotropin β-subunits, and thus are gonadotrope-derived (Luteinizing Hormone, Follicle-Stimulating Hormone, and Human Chorionic Gonadotropin). Rarely, both α- and β-subunits are secreted as functional dimeric hormone.

PITUITARY ADENOMA SYMPTOMS

Endocrinopathy

Pituitary adenomas may cause symptoms via excess hormone secretion and lead to clinical conditions such as hyperprolactinemia, acromegaly, or Cushing disease. Alternatively, adenomas may result in hormone deficiency due to damage of other pituitary cell types or of the pituitary stalk by an expanding adenoma or following treatment of the primary lesion.

As might be predicted, pituitary microadenomas are typically diagnosed during evaluation of an endocrinopathy, whereas macroadenomas frequently come to medical attention when a patient presents with symptoms from invasion of surrounding structures. The anterior pituitary gland borders both the optic chiasm and cavernous sinus. Disruption of the optic chiasm by suprasellar growth of the pituitary mass may present as bitemporal hemianopsia in which patients lose of the outer portion of the

right and left visual fields. Cavernous sinus syndrome consists of a constellation of symptoms including headache, visual disturbances, and cranial nerve palsies, specifically cranial nerves III, IV, and VI.

Pituitary Apoplexy

Spontaneous hemorrhage into a pituitary adenoma, termed *pituitary apoplexy,* is a rare life-threatening medical emergency. Apoplexy may lead to severe hypoglycemia, hypotension, CNS hemorrhage, and death. Signs and symptoms include acute visual changes, severe headache, neck stiffness, hypotension, loss of consciousness, and coma. These symptoms result from: (1) leakage of blood and necrotic material into the subarachnoid space, (2) acute hypopituitarism, and (3) development of a rapidly expanding hemorrhagic intrasellar mass that compresses the optic chiasm, cranial nerves, hypothalamus, and/or internal carotid arteries.

Reproductive Effects

Any pituitary mass or infiltrate can present as an abnormality in reproductive function that may include delayed puberty, anovulation, oligomenorrhea, and infertility. The exact mechanisms linking adenomas to menstrual dysfunction are not well understood for many adenoma subtypes, perhaps with the exception of prolactinoma. Hyperprolactinemia results in a reflex increase in central dopamine. Stimulation of the dopaminergic receptors on the GnRH neurons alters GnRH pulsatility, thereby disrupting folliculogenesis. It has been postulated that non-prolactin-secreting adenomas may affect reproductive function either by compressing the pituitary stalk with resultant hyperprolactinemia or by directly compressing gonadotropes. Additional mechanisms undoubtedly exist in view of the complexity of the interactions between the various hormones, peptides, and neurotransmitters that influence hypothalamic function.

PITUITARY ADENOMA DIAGNOSIS

The availability of sensitive neuroimaging techniques now affords earlier diagnosis and intervention. In the past, pituitary adenomas were identified using a coned-down view of the sella turcica during standard head radiography. Although computed tomographic (CT) scanning provides useful information on tumor size, bony artifacts may limit interpretation. Therefore magnetic resonance (MR) imaging, using both T1- and T2-weighted images, has become the primary radiologic method due to its high sensitivity and excellent spatial resolution (Ruscalleda, 2005). Frequently, MR imaging is performed with and without gadolinium infusion for maximum definition of tumor size and extension.

TREATMENT OF PITUITARY ADENOMAS

Specifically, for those with prolactin-secreting adenomas, most tumors grow slowly, and many cease growth after attainment of a certain size. Thus, asymptomatic patients with a microprolactinoma may be managed conservatively with serial MR imaging and serum PRL levels every 1 to 2 years, as the risk of progression to a macroadenoma is less than 10 percent (Schlechte, 1989). These women should be followed for even mild changes in menstrual cyclicity, as they are at risk for developing hypoestrogenism and resultant risk for osteopenia or osteoporosis (Klibanski, 1980).

When tumors of any size are associated with symptoms of amenorrhea or galactorrhea, therapy should be considered (Fig. 15-10). Neurosurgical evaluation is mandatory when visual field defects or severe headaches are present. In general, first-line treatment is medical for both micro- and macroadenomas. Specifically, women should receive a dopamine agonist such as the nonspecific dopamine receptor agonist, bromocriptine (Parlodel, Novartis, Novartis Pharmaceuticals, East Hanover, NJ), or the dopamine receptor type 2 agonist, cabergoline (Dostinex, Pfizer, New York, NY).

These dopamine agonists decrease PRL secretion and shrink tumor size (Molitch, 2001). However, bromocriptine treatment is associated with a number of common side effects including headache, postural hypotension, blurred vision, drowsiness, and leg cramps. Most of these are attributable to activation of type 1 dopamine receptors. Due to its receptor specificity, cabergoline treatment is generally better tolerated than bromocriptine. Cabergoline also has a longer half-life than bromocriptine, allowing once- or twice-weekly dosing compared with the multiple daily doses that may be required for bromocriptine. Typical initial cabergoline dosages are 0.25 mg orally daily twice weekly. Cabergoline has been found to be more effective than bromocriptine in normalizing PRL levels (Di Sarno, 2001; Webster, 1994). Nevertheless, cabergoline can be prohibitively expensive. Most patients

can tolerate bromocriptine if started at a low doseâ€”Â½ tablet or 0.125 mgâ€”each night to minimize associated nausea and dizziness. This dose can be slowly increased to three times daily as tolerated. Reliable measurement of posttreatment serum prolactin levels can be obtained 1 month following a steady medication dose.

Surgery

Neurosurgery is required for refractory tumors or those causing acutely worsening symptoms. The pituitary is approached through a transsphenoidal route whenever possible (Fig. 15-11). Complications of surgery, although rare, include intraoperative hemorrhage, a cerebrospinal fluid leak (rhinorrhea), diabetes insipidus, damage to other pituitary cell types, and meningitis (Arafah, 1986; Molitch, 1999). Radiation therapy may be used for patients with surgically nonresectable or persistent tumors.

Other Treatments

Depending on the success of these approaches, additional therapies such as radiation therapy may be required to manage residual symptoms. The gamma knife allows precise focus of the radiation beam, significantly decreasing adjacent tissue damage and improving patient tolerance.

Gene therapy has been proposed as a treatment for pituitary tumors. Possibilities include the introduction of genes that encode growth-inhibiting factors by retroviral infection. Additional studies are needed to determine whether this approach will be safe and efficacious (Seilicovich, 2005).

PREGNANCY AND PITUITARY ADENOMAS

The pituitary gland enlarges during pregnancy, primarily due to hypertrophy and hyperplasia of the lactotropes in response to elevated serum estrogen levels. Although there is a risk of tumor enlargement during pregnancy, clinical experience has shown that the risk is small, particularly for microadenomas (Molitch, 1985, 1999). However, because significant expansion may lead to headaches or compression of the optic chiasm and blindness, visual field testing should be considered every trimester for women with macroadenomas. Although it is likely to be safe, most experts advise that dopamine agonist therapy be discontinued during pregnancy (Webster, 1996).

HORMONE BIOSYNTHESIS AND MECHANISM OF ACTION

Hormones can be broadly classified as either steroids or peptides, each with their own mode of biosynthesis and mechanism of

action. These hormones' receptors can be divided into two groups: (1) those present on the cell surface, which in general interact with hormones that are water soluble, namely peptides, and (2) those that are primarily intracellular and interact with lipophilic hormones such as steroids. Hormones are normally present in serum and tissues in very low concentrations. Therefore, receptors must have both high affinity and high specificity for their ligand to produce the correct biologic response.

Peptide Hormones in Reproduction

LUTEINIZING HORMONE, FOLLICLE-STIMULATING HORMONE, AND HUMAN CHORIONIC GONADOTROPIN

Structurally, LH and FSH are heterodimers that contain a common α-subunit linked to either the LHβ or FSHβ subunit, respectively. The common glycoprotein α-subunit also interacts with the thyrotropin-stimulating hormone β-subunit to form TSH, and with the human chorionic gonadotropin β-subunit to form hCG. The similarity of these hormones can have clinical sequelae. For example, molar pregnancies frequently produce very high levels of hCG, which can bind to TSH receptors, producing hyperthyroidism. Importantly, only the dimers possess biologic activity. Although the subunits can be found in their unassociated form in the circulation, these "free" subunits are not known to have physiologic significance.

The LH and hCG β-subunits are encoded by two separate genes within a gene grouping called the LH/CG cluster. The amino acid sequence of the human LH and CG β-subunits demonstrates approximately 80 percent similarity. However, the hCG β-subunit contains an additional 24-amino-acid extension on the carboxy terminus. The presence of these additional amino acids has allowed the development of highly specific assays for both LH and hCG.

ACTIVIN, INHIBIN, AND FOLLISTATIN

Three polypeptide factorsâ€”*inhibin, activin,* and *follistatin* â€”were initially isolated from follicular fluid and named based on their selective effects on FSH biosynthesis and secretion (Halvorson, 1996). Inhibin decreases and activin stimulates gonadotrope function. Follistatin suppresses FSHβ gene expression, most likely by binding to and thereby preventing the interaction of activin with its receptor (Besecke, 1997; Kogawa, 1991). Subsequent studies have indicated that these peptides also affect biosynthesis of LH and the GnRH receptor, although these responses are less robust (Kaiser, 1997).

Inhibin and activin are closely related peptides. Inhibin consists of an α-subunit (unrelated to the LH glycoprotein α-subunit) linked by a disulfide bridge to one of two highly homologous β-subunits to form inhibin A ($\alpha\beta_A$) or inhibin B ($\alpha\beta_B$). Activin is composed of homodimers ($\beta_A\ \beta_A$, $\beta_B\ \beta_B$) or heterodimers ($\beta_A\ \beta_B$) of the same β-subunits as inhibin (Dye, 1992; Halvorson, 1996). More recently, a number of additional β-subunit isoforms have been identified. In contrast, follistatin is structurally unrelated to either inhibin or activin.

Although originally isolated from follicular fluid, these "gonadal" peptides are expressed by a wide variety of reproductive tissues in which they provide diverse, tissue-specific functions (Meunier, 1988). The mRNAs that encode the inhibin/activin subunits, follistatin, and the activin receptor have been detected in the pituitary, ovary, testes, and placenta, as well as in the brain, adrenal, liver, kidney, and bone marrow (Kaiser, 1992).

Of these peptides, inhibin is currently believed to be most critical for the feedback regulation of gonadotropin gene expression. In contrast, activin and follistatin effects on gonadotrope function most likely occur through the action of locally released peptides acting as autocrine/paracrine factors.

Steroid Hormones in Reproduction

BIOSYNTHESIS AND METABOLISM

Sex steroid hormones are synthesized in the gonads, adrenal gland, and placenta. Cholesterol is the primary building block in steroidogenesis, and all steroid-producing tissues except the placenta are capable of synthesizing cholesterol from the 2-carbon precursor, acetate. Steroid hormone production, which involves at least 17 enzymes, primarily occurs in the abundant smooth endoplasmic reticulum found in steroidogenic cells (Mason, 2002).

Steroids are metabolized mainly in the liver and to a lesser extent in the kidney and intestinal mucosa. Accordingly, administration of certain pharmacologic steroid hormones may be contraindicated in those with active liver disease.

STEROID HORMONE CLASSIFICATION

Sex steroids are divided into three groups based on the number of carbon atoms that they contain. Each carbon in this structure is assigned a number identifier, and each ring is assigned a letter (Fig. 15-12). The 21-carbon series includes progestins as well as glucocorticoids and mineralocorticoids. Androgens contain 19 carbons, whereas estrogens have 18.

FIGURE 15-12

Diagram displays the chemical structure of cholesterol, which is the common precursor in sex steroid biosynthesis. All sex steroids contain the basic cyclopentanephenanthrene molecule, which consists of three 6-carbon rings and one 5-carbon ring. *(From Carr, 2005b, with permission.)*

Steroids are accorded scientific names according to a generally accepted convention in which functional groups below the plane of the molecule are preceded by the α symbol and those above the plane of the molecule are indicated by a β symbol. A Δ symbol indicates a double bond. Those steroids with a double bond between carbon atoms 5 and 6 are called Δ^5 steroids (pregnenolone, 17-hydroxypregnenolone, and dehydroepiandrosterone). Those with a double bond between carbons 4 and 5 are termed Δ^4 steroids (progesterone, 17-hydroxyprogesterone, androstenedione, testosterone, mineralocorticoids, and glucocorticoids).

Steroidogenic enzymes catalyze four basic modifications of the steroid structure: (1) side-chain cleavage (desmolase reaction), (2) conversion of hydroxyl groups to ketones (dehydrogenase reactions), (3) addition of a hydroxyl group (hydroxylation reaction), and (4) removal or addition of hydrogen to create or reduce a double bond (Table 15-3). The steroid biosynthesis pathway is shown in simplified form in Fig. 15-13. The distribution of products synthesized by each tissue is determined by the presence of requisite enzymes. For example, the ovary is deficient in 21-hydroxylase and 11β-hydroxylase and therefore is unable to produce corticosteroids.

CLINICAL EFFECT OF CERTAIN STEROIDOGENIC STEPS

Congenital Adrenal Hyperplasia

Typically due to a 21-hydroxylase deficiency, classic congenital adrenal hyperplasia (CAH) is one of the most common autosomal recessive metabolic diseases, estimated to occur in 1:10,000 to 1:15,000 births. Although CAH has been reported in a wide range of ethnic groups, it is most common in the Ashkenazi Jewish population. Alternatively, deficiencies in 11β-hydroxylase activity account for 5 to 8 percent of CAH cases.

Patients with CAH exhibit a broad range of clinical phenotypes depending on the extent of enzymatic deficiency. On one extreme, gene conversions and large deletions lead to severe enzyme deficiency and present as salt-wasting CAH in the neonate. Moreover, in this form of CAH, a block at the 21-hydroxylase step results in markedly reduced levels of aldosterone and cortisol. The back-up of precursors shifts steroidogenesis towards the androgen pathway. Therefore, females with CAH may present with female pseudohermaphroditism (female karyotype with masculinized external genitalia) (see Chap. 18, Congenital Ambiguity of the Genital Tract). Unless replaced with corticosteroids, these neonates will die shortly after birth. A less severe mutation may lead to simple virilizing CAH. As its name suggests, this condition is notable for sufficient corticosteroid production but increased androgen levels.

In a nonclassic form of CAH, also known as late-onset or adult-onset CAH, hyperandrogenemia does not present until puberty. The incidence of nonclassic disease has been estimated at 1:1,000 births. At puberty, activation of the adrenal axis increases

steroidogenesis, unmasking a mild 21-hydroxylase activity deficiency. Levels of ACTH may increase due to the lack of negative feedback by cortisol, further exacerbating androgen production. These patients often present with hirsutism, acne, and anovulation. Thus, late-onset CAH may mimic polycystic ovarian syndrome (PCOS).

Diagnostically, serum 17-hydroxyprogesterone (17-OH-P) levels provide a sensitive screen for the presence of CAH. Levels should be measured during the follicular phase to avoid false-positives from 17-OH-P secretion by the corpus luteum.

Synthesis of Estrogens from Androgens

Aromatization of C19 androgens by P450arom (aromatase; CYP19) yields C18 estrogens containing a phenolic ring (see Fig. 10-1). In addition to the ovary, aromatase is expressed in significant levels in adipose tissue, skin, and brain (Simpson, 1997). Clinically important, sufficient estrogen can be derived from peripheral aromatization to produce endometrial bleeding in postmenopausal women, especially those who are overweight or obese.

5α-Reductase Types 1 and 2

The 5α-reductase enzyme exists in two forms, each encoded by a separate gene. The type 1 enzyme is found in the liver, kidneys, skin, and brain. In contrast, the type 2 enzyme is predominantly expressed in the male genitalia (Russell, 1994; Wilson, 1993). 5α-reductase converts testosterone to a more potent androgen, 5α-dihydrotestosterone (DHT). Because DHT promotes transformation of vellus hair to terminal hair, medications that antagonize 5α-reductase are often effective in the treatment of hirsutism (see Chap. 17, Hirsutism).

DERIVATION OF CIRCULATING ESTROGENS IN THE FEMALE

Circulating estrogens in the reproductive-aged female are a mixture of both estradiol and the less potent estrone. Although a small amount of estriol is produced through peripheral conversion in the nonpregnant female, estriol production is primarily limited to production by the placenta during pregnancy.

Estradiol is the primary estrogen produced by the ovary during reproductive years. Levels are derived from both direct synthesis in developing follicles and through conversion of estrone. Estrone is secreted directly by the ovary and can be converted from androstenedione in the periphery. Androgens are converted to estrogens in many tissues, but mainly result from aromatase activity in skin and adipose tissue.

The ovary produces primarily androstenedione and dehydroepiandrosterone (DHEA) with small amounts of testosterone. Although the adrenal cortex primarily produces mineralocorticoids and glucocorticoids, it also contributes to approximately one-half of the daily production of androstenedione, DHEA, and essentially all of the sulfated form of DHEA (DHEAS). Twenty-five percent of circulating testosterone is secreted by the ovary, 25 percent is secreted by the adrenal gland, and the remaining 50 percent is produced by peripheral conversion of androstenedione to testosterone (Fig. 15-14) (Silva, 1987).

STEROID SYNTHESIS IN THE ADRENAL GLAND

The adult adrenal gland is composed of three zones. Each of these zones expresses a different complement of steroidogenic enzymes and as a result, synthesizes different products. The zona glomerulosa lacks 17α-hydroxylase activity but contains large amounts of aldosterone synthase (P450aldo) and therefore produces mineralocorticoids. As noted earlier, the zona fasciculata and zona reticularis, both of which express the 17α-hydroxylase gene, synthesize glucocorticoids and androgens, respectively (Corticotropin-Releasing Hormone).

STEROID HORMONE TRANSPORT IN THE CIRCULATION

Most steroids in the peripheral circulation are bound to carrier proteins, either specific proteins such as sex-hormone binding globulin (SHBG) or corticosteroid-binding globulin, or to nonspecific proteins such as albumin. Only 1 to 2 percent of androgens and estrogens are unbound or free.

Only the unbound steroid fraction is believed to be biologically active, although albumin's low affinity for sex steroids may allow steroids bound to this protein to exert some effects. The amount of free hormone is in equilibrium with the amount bound. As a result, small changes in carrier protein expression can produce substantial alterations in steroid effect.

Sex-hormone binding globulin (SHBG) circulates as a homodimer that binds a single steroid molecule. This binding protein is primarily synthesized in the liver, although it has also been detected in other tissues such as the brain, placenta, endometrium, and testes (Hammond, 1989, 1996). Levels of SHBG are increased by hyperthyroidism, pregnancy, and estrogen administration. In contrast, androgens, progestins, GH, insulin, and corticoids decrease SHBG levels. An increase in weight, particularly central body fat, can significantly blunt SHBG expression and thereby increase free hormone levels.

Note that unbound hormone can be technically difficult to measure and results should be interpreted with caution. Free testosterone levels are the most commonly ordered free steroid hormone tests. The most accurate assays require dialysis of the sample and are performed by a limited number of commercial laboratories. The more widely available calculated free levels are relatively inaccurate. Unlike thyroid hormone measurements, the measurement of free testosterone is rarely necessary for clinical diagnosis in the female. For example, measurement of testosterone levels in patients with presumed PCOS are important for eliminating the presence of an androgen-producing tumor. Normal or high-normal levels of total testosterone are consistent with the diagnosis of PCOS. Because testosterone decreases SHBG levels, patients with normal total testosterone levels but clinical evidence of hyperandrogenism (hirsutism and/or acne), invariably have either increased free testosterone levels or increased sensitivity of the hair follicle and sebaceous glands.

RECEPTOR STRUCTURE AND FUNCTION

Steroid hormones and peptide factors differ in their specific DNA interaction, yet both ultimately lead to DNA transcription and protein production. In the nucleus, steroid-bound receptors bind to DNA-regulatory elements within target-gene promoter regions. In the case of peptide factors, sequential phosphorylation ultimately activates proteins bound to gene promoter sequences. In either case, following gene activation, the enzyme ribonucleic acid (RNA) polymerase transcribes the information into messenger ribonucleic acid (mRNA), which carries the coded information into the cytoplasmic compartment of cells. There, the information is translated by ribosomes into proteins.

G-Protein Coupled Receptors

INTRACELLULAR SIGNALING SYSTEMS

G-protein coupled receptors are a large family of cell membrane associated receptors that bind peptide factors. These receptors consist of a hydrophilic extracellular domain, an intracellular domain, and a hydrophobic transmembrane domain that spans the cell membrane seven times. When bound to hormone, these receptors undergo a conformational change, activate intracellular signaling pathways, and through a series of phosphorylation events, ultimately modulate transcription of multiple genes within the target cell.

GONADOTROPIN-RELEASING HORMONE RECEPTOR

The GnRH receptor (GnRH-R) is a member of the G-protein coupled receptor superfamily. Expression of GnRH-R has been identified in the ovary, testes, hypothalamus, prostate, breast, and placenta. Gonadotropin-releasing hormone itself may also be expressed in the pituitary, gonads, and placenta. Although data are still preliminary, GnRH and its receptor may form an autocrine/paracrine regulatory network in reproductive tissues, besides the classic neuroendocrine hypothalamic-pituitary system.

GONADOTROPIN RECEPTORS

Both LH and hCG bind to a single G-protein coupled receptor known as the LH/CG receptor. Relative to LH, hCG has a slightly higher affinity for the receptor and has a longer half-life. In contrast, FSH binds to a unique G-protein coupled receptor.

Within the ovary, the LH/CG receptor is expressed on thecal cells, interstitial cells, and luteal cells. In the granulosa cells of preantral follicles, LH/CG receptor mRNA is nearly undetectable. Expression of this receptor is markedly induced during follicular maturation, with high levels observed in differentiated granulosa cells. LH/CG receptors have been identified in the human endometrium, myometrium, fallopian tubes, and brain (Camp, 1991). The function of the LH/CG ligand-receptor system is unknown for these other tissues. In contrast, FSH receptor expression appears to be restricted to the granulosa cells of the ovary and the Sertoli cells of the testis.

Steroid Hormone Receptors

CLASSIFICATION OF STEROID RECEPTOR SUPERFAMILY MEMBERS

Despite their structural similarities, estrogens, progestins, androgens, mineralocorticoids, and glucocorticoids all interact with unique receptors known as nuclear hormone receptors. The nuclear receptor superfamily consists of three receptor groups: (1) those that bind steroidal ligands, (2) those that have affinity for nonsteroidal ligands, and (3) those with no known ligand. In the

first group, receptors are gene transcription factors with known steroidal ligands, such as estrogen, progesterone, and androgens. The second group contains nonsteroid ligand-activated receptors such as thyroid hormone and retinoic acid receptors. Lastly, orphan receptors comprise the largest component of the nuclear receptor superfamily. By definition, these receptors do not have an identified ligand and may be constitutively active.

MODULAR STRUCTURE OF THE STEROID RECEPTOR SUPERFAMILY

Free steroids diffuse into cells and combine with specific receptors (Fig. 15-15). Subsequently, steroid receptors enhance or repress gene transcription through interactions with specific DNA sequences, called hormone responsive elements, in the promoter region of target genes (Klinge, 2001). Members of this receptor superfamily exhibit a modular structure of distinct domains as depicted in Fig. 15-16. Each of these regions provides activities required for full receptor function.

FIGURE 15-15

Diagram illustrates interaction between cells and steroid hormones. Most hormones circulate bound to carrier serum binding proteins. Unbound hormones are free to bind with empty steroid receptors found either in the cytoplasm or more commonly, in the cell's nucleus. Hormone-bound receptors then bind to specific DNA promoter sequences. This binding typically leads to DNA transcription and eventually to specific protein synthesis. *(From Bulun, 2005, with permission.)*

Drawing depicts the concept of functional domains within estrogen and progesterone receptors. Note distinct sites for ligand and DNA binding. *(Redrawn from O'Malley, 1999, with permission.)*

In general, nuclear receptors have two regions that are critical for gene activation, termed activation function 1 and activation function 2 (AF1 and AF2). AF1 is located in the A/B domain and is usually ligand-independent. AF2 is in the ligand-binding domain (E) and is often hormone-dependent. The highly conserved DNA-binding region (C) consists of "zinc fingers", so-called because the presence of zinc introduces a loop in the amino acid sequence, creating a structure that inserts into the DNA helix.

ESTROGEN, PROGESTERONE, AND ANDROGEN RECEPTORS

Receptors for estrogen are localized to the nucleus. In contrast, progesterone receptors (PRs), androgen receptors (ARs), and those for mineralocorticoids and glucocorticoids are cytoplasmic in the absence of ligand. Ligand binding to these latter receptors allows translocation to the nucleus.

Two isoforms of estrogen receptors, ERα and ERβ, have been cloned and are encoded by separate genes. These receptors are differentially expressed in tissues and appear to subserve distinct functions (Kuiper, 1997). For example, both ERα and ERβ are required for normal ovarian function. However, mice lacking ERα are anovulatory and accumulate cystic follicles, whereas the ovaries of ERβ null mice are normal histologically despite impaired ovulation (Couse, 2000).

The progesterone receptor (PR) also exists in at least two isoforms. Encoded from a single gene, PRA and PRB are identical except for an additional 164 amino acids at the amino terminus (Conneely, 2002). A third PR isoform, designated PRC, differs from the other two in its DNA-binding domain and has been postulated to act as a progestin inhibitor (Wei, 1996). As with the estrogen receptors, the PR isoforms are not interchangeable. For example, PRA is required for normal ovarian and uterine functions but is

expendable in the breast (Lydon, 1996).

Only one form of the androgen receptor (AR) has been identified. This receptor contains the classic steroid receptor structure. Mutations in this receptor are responsible for the syndrome of androgen insensitivity in 46,XY patients characterized by lack of sexual hair, absence of a uterus and fallopian tubes, and presence of a vaginal pouch, and intra-abdominal testes (see Chap. 18, Pathophysiology) (Brinkmann, 2001).

Nongenomic Actions of Steroids

Recent studies have introduced the concept that a subset of steroids, including estrogens and progestins, may alter cell function via nongenomic effects, that is, independent of the classic nuclear hormone receptors. These nongenomic effects occur rapidly and may be mediated via cell-surface receptors (Moore, 1999). Pharmacologic agents under development specifically target these nongenomic effects to allow more precise therapy for steroid-sensitive disorders.

Receptor Regulation

Many factors modulate the cellular response to sex steroids and peptide factors. Of these, the number of receptors within a cell or on the cell membrane is critical for attaining a maximal hormonal response. Importantly, the number of receptors cell can be modified at multiple levels of gene expression from gene transcription through receptor protein degradation.

DESENSITIZATION

Hormonally-induced negative regulation of receptors is termed *homologous downregulation* or *desensitization* . Desensitization provides a mechanism for limiting the duration of a hormonal response by decreasing the sensitivity of a cell to a constant level of hormone upon prolonged exposure.

Within the reproductive system, the process of desensitization is best understood for the GnRH receptor and is used clinically to produce a hypoestrogenic state. Pharmacologic agonists of GnRH initially stimulate receptors on pituitary gonadotropes to cause a supraphysiologic release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (see Chap. 9, GnRH Agonists). With their long-term action, however, agonists downregulate receptors in gonadotropes, thus impairing sensitivity to further GnRH stimulation. Correspondingly, decreased gonadotropin secretion leads to suppressed estrogen and progesterone levels 1 to 2 weeks after initial GnRH agonist administration.

HORMONE MEASUREMENT

Potential Measurement Inaccuracy

Immunoassays have been developed for essentially all polypeptide, steroid, and thyroid hormones. These assays are remarkably sensitive, and in most cases are easily automated. For many hormones, the concentration is reported as International Units per volume rather than as a mass per volume (Table 15-4). It is critical to know which reference standard is used by a specific assay, as results may differ significantly. Reference preparations are produced by the World Health Organization (WHO) or by the National Institutes of Health (NIH). Over 20 standards are available for measurement of LH, FSH, PRL, and hCG. Clinically, this issue may arise in a patient with a possible ectopic pregnancy in which serial β-hCG levels are being obtained at different health care facilities.

The possibility of a "hook effect" should also be considered in the interpretation of results. In the presence of very high hormone levels, antibody binding will be saturated and can give a falsely low reading.

In addition, the amount of immunoreactive hormone present in a sample does not necessarily correlate with the biologic activity of that hormone. For example, PRL exists in multiple isoforms, many of which are immunologically detectable, but not biologically

active. Similarly, alternate glycosylation patterns of the gonadotropins at different times of the reproductive life span are believed to alter their biologic activity.

"Normal" ranges should also be interpreted with care, as a stated normal range is often broad. An individual may have a doubling of their hormone level, and the level may still lie within a normal range, although the result is actually abnormal for that individual.

In the context of the pituitary gland and its target endocrine glands, it may be adequate to measure the pituitary hormone alone. However, interpretation of the result may be clarified by the addition of the target hormone level. For example, in many laboratories, an abnormal TSH value will lead to "reflex" testing for thyroid hormone levels. Low levels of both members of a stimulating-hormone and target-gland hormone pair indicate an abnormality in either hypothalamic or pituitary function (Table 15-5). High levels of a target-gland hormone coupled with low levels of its stimulating pituitary hormone suggest autonomous secretion by the target organ, such as that which occurs in the hyperthyroidism of Graves disease.

Stimulation Tests

These tests may be used when hypofunction of an endocrine organ is suspected. These tests use a known endogenous stimulating hormone to assess the reserve capacity of the tissue of interest. The trophic hormone used may be a hypothalamic releasing factor such as GnRH or TRH, or a substitute pituitary hormone such as hCG for LH or cortrysyn for ACTH. The ability of the target gland to respond is measured by an increase in the appropriate hormone's plasma level. The "GnRH stim" test may be useful in evaluation of delayed puberty (see Chap. 14, Central Precocious Puberty (Gonadotropin-Dependent)). Unfortunately, clinical grade GnRH is often unavailable.

Suppression Tests

These tests may be performed when endocrine hyperfunction is suspected. For example, a dexamethasone suppression test may be given to a patient with suspected hypercortisolism (Cushing disease or syndrome) to gauge the ability of this treatment to inhibit ACTH secretion and thus cortisol production by the adrenal (see Chap. 17, Cortisol). The failure of glucocorticoid treatment to suppress cortisol production would be consistent with primary hyperadrenalism.

MENSTRUAL CYCLE

The typical menstrual cycle is defined as 28 Â± 7 days, with menstrual flow lasting 4 Â± 2 days, and an average blood loss of 20 to 60 mL. By convention, the first day of vaginal bleeding is considered day 1 of the menstrual cycle. Menstrual cycle intervals vary among women and often for an individual woman at different times of her reproductive life (Fig. 15-17). In a study of more than 2,700 women, menstrual cycle interval was most irregular in the 2 years following menarche and the 3 years preceding menopause (Treloar, 1967). The menstrual cycle is least variable between the ages of 20 and 40 years. Specifically, a trend toward shorter intervals is common during early menopausal transition, but is followed by interval lengthening in later transition (see Chap. 21, Definitions).

When viewed from a perspective of ovarian function, the menstrual cycle can be divided into a pre-ovulatory follicular phase and postovulatory luteal phase (Fig. 15-18). Corresponding phases in the endometrium are termed the proliferative and secretory phases (Table 15-6). For most women, the luteal phase of the menstrual cycle is stable, lasting 13 to 14 days. Thus, variations in normal cycle length generally result from variations in follicular phase duration (Ferin, 1974).

THE OVARY

Ovarian Morphology

The adult human ovary is oval with a length of 2 to 5 cm, a width of 1.5 to 3 cm, and a thickness of 0.5 to 1.5 cm. During the reproductive years, ovaries weigh between 5 and 10 g. They are comprised of three parts: an outer cortical region, which contains both the germinal epithelium and the follicles; a medullary region, which consists of connective tissue, myoid-like contractile cells, and interstitial cells; and a hilum, which contains blood vessels, lymphatics and nerves that enter the ovary (Fig. 15-19).

Ovaries have two interrelated functions: the production of oocytes and the production of steroid and peptide hormones that create an environment in which fertilization and subsequent implantation in the endometrium can occur. Endocrine functions of the ovary correlate closely with the morphologic appearance and disappearance of follicles and corpus luteum.

Embryology of the Ovary

The ovary develops from three major cellular sources: (1) primordial germ cells, which arise from the endoderm of the yolk sac and differentiate into the primary oogonium, (2) coelomic epithelial cells, which develop into granulosa cells, and (3) mesenchymal cells from the gonadal ridge, which become the ovarian stroma.

Primordial germ cells can be identified in the yolk sac as early as the third week of gestation (Baker, 1963). These cells begin their migration into the gonadal ridge during the sixth week of gestation and generate the primary sex cords (see Fig. 18-2). It is not possible to distinguish the ovary from the testes by histologic criteria until approximately 10 to 11 weeks of fetal life.

After the primordial cells reach the gonad, they continue to multiply through successive mitotic divisions. Starting at 12 weeks' gestation, a subset of oogonia will enter meiosis to become primary oocytes (Baker, 1967). Primary oocytes are surrounded by a single layer of flattened granulosa cells, creating a primordial follicle.

The Ovary Across the Reproductive Life Span

All oogonia either develop into primary oocytes or become atretic. Based on our current understanding of ovarian function, additional oocytes cannot be generated postnatally. This differs markedly from the male situation in which sperm are produced continuously throughout adulthood.

The maximal number of oogonia is achieved at the 20th week of gestation, at which time six to seven million oogonia are present in the ovary (Baker, 1963). Approximately one to two million oogonia are present at birth with less than 400,000 present at the initiation of puberty, of which less than 500 are destined to ovulate (Peters, 1978). Therefore, most female germ cells are lost

through atresia (see Fig. 14-1) (Hsueh, 1996).

There is now strong evidence that follicular atresia is not a passive, necrotic process, but rather a precisely controlled active process, namely apoptosis, which is under hormonal control. Apoptosis begins in utero and continues throughout reproductive life.

Meiotic Division during Oocyte Maturation

As previously mentioned, primary oogonia enter meiosis in utero to become primary oocytes. These oocytes are arrested in development at prophase I during the first meiotic division. Meiotic division resumes at ovulation in response to the LH surge. Once again, the process is arrested. The arrest of meiosis prior to ovulation is believed to be due to production of an oocyte maturation inhibitor (OMI) by the granulosa cells (Tsafriri, 1982). Meiosis is completed only if fertilization occurs (Fig. 15-20).

FIGURE 15-20

Drawing illustrates the steps of meiosis and the corresponding stages of oocyte development. In the fetal period, mitotic division of oocytes produces primary oocytes. Primary oocytes begin meiosis, but the process arrests in the first meiotic prophase. In childhood, primary oocytes

remain suspended in prophase I. Beginning in puberty and extending through the reproductive years, several primordial follicles mature each month into primary follicles. A few of these continue development to secondary follicles. One or two secondary follicles progress to a tertiary or graafian follicle stage. At this stage, the first meiotic division occurs to produce a haploid secondary oocyte and a polar body. During this process, cytoplasm is conserved by the secondary oocyte, and consequently the polar body is disproportionately small. The secondary oocyte halts meiosis at its second metaphase. One of the secondary oocytes is released at ovulation. If the oocyte is fertilized, then completion of the second meiotic division follows. If fertilization fails to occur, then the oocyte degenerates prior to completion of the second meiotic division. *(From McKinley, 2006, with permission.)*

Completion of the first meiotic division within the oocyte results in production of a polar body, which contains chromosomal material but minimal cytoplasm. With completion of meiosis following fertilization, a second polar body is extruded. The maternal nucleus, called a pronucleus, fuses with the paternal pronucleus to generate a pre-embryo with a 46,XX or 46,XY karyotype (Felig, 1987).

Stromal Cells

Ovarian stroma contains interstitial cells, connective tissue cells, and contractile cells. Of these, connective tissue cells provide structural support to the ovary. Interstitial cells surrounding a developing follicle differentiate into theca cells. Under gonadotropin stimulation, these cells increase in size and develop lipid stores, which are characteristic of steroid-producing cells (Saxena, 1972).

Another group of interstitial cells is present in the ovarian hilum and therefore are known as hilus cells. These cells closely resemble testicular Leydig cells, and hyperplasia or neoplastic changes in hilar cells may result in virilization from excess testosterone secretion. The normal role of these cells is unknown, but their intimate association with blood vessels and neurons suggest that they may convey systemic signals to the remainder of the ovary (Upadhyay, 1982).

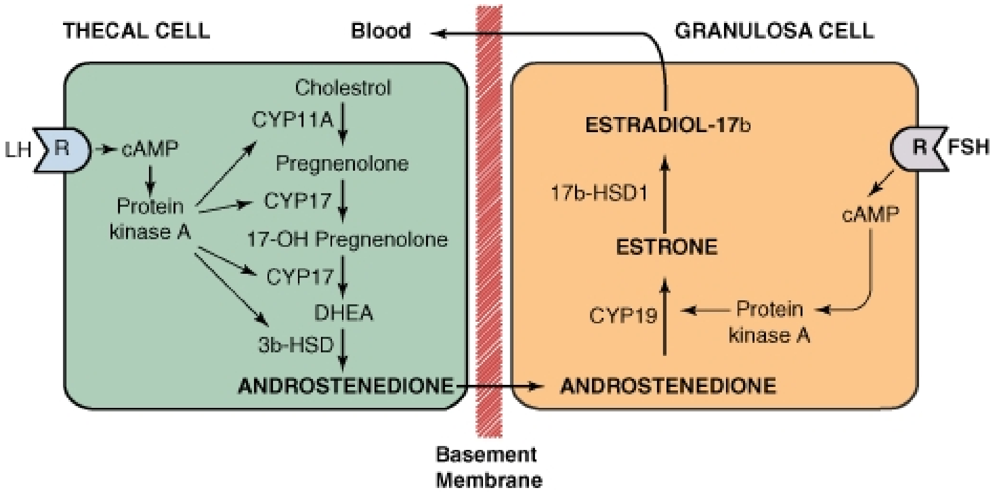
Ovarian Steroidogenesis

The normal functioning ovary synthesizes and secretes the sex-steroid hormonesâ€”estrogens, androgens, and progesterone, in a precisely controlled pattern determined in part by the pituitary gonadotropins, FSH and LH. The most important secretory products of ovarian steroid biosynthesis are progesterone and estradiol. However, the ovary also secretes quantities of estrone, androstenedione, testosterone, and 17-hydroxyprogesterone. Sex-steroid hormones play an important role in the menstrual cycle by preparing the uterus for implantation of a fertilized ovum. If implantation does not occur, ovarian steroidogenesis declines, the endometrium degenerates, and menstruation ensues.

TWO-CELL THEORY OF OVARIAN STEROIDOGENESIS

First proposed by Falck in 1959, the two-cell theory of ovarian steroidogenesis explains that estrogen biosynthesis requires the combined action of two gonadotropins (LH and FSH) on two cell types (theca and granulosa cells) (Fig. 15-21) (Peters, 1980). Until the late antral stage of follicular development, LH-receptor expression is limited to the thecal compartment and FSH-receptor expression is limited to the granulosa cells.

FIGURE 15-21



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Diagram illustrates the two-cell theory of ovarian follicular steroidogenesis. Theca cells contain large numbers of luteinizing hormone (LH) receptors (R). Binding of LH to these receptors leads to cyclic AMP activation and synthesis of androstenedione from cholesterol. Androstenedione diffuses across the basement membrane of theca cells to enter granulosa cells of the ovary. Here, under the activation of follicle-stimulating hormone (FSH), androstenedione is converted by the enzyme aromatase to estrone and estradiol. cAMP = cyclic adenosine monophosphate; CYP11A = cholesterol side-chain cleavage enzyme; CYP17 = 17α-hydroxylase; CYP19 = aromatase; DHEA = dehydroepiandrosterone; 3β-HSD = 3β-hydroxysteroid dehydrogenase; 17β-HSD1 = 17β-hydroxysteroid dehydrogenase; R = receptor. *(From Carr, 2005a, with permission.)*

Theca cells express all of the genes needed to produce androstenedione. This includes high levels of *CYP17* gene expression, whose enzyme product catalyzes 17-hydroxylationâ€"the rate-limiting step in the conversion of progesterones to androgens (Sasano, 1989). This enzyme is absent in the granulosa cells, so they are incapable of producing the precursor needed to produce estrogens by themselves. Granulosa cells therefore rely on the theca cells as their primary source for estrogen precursors.

In response to LH stimulation, theca cells synthesize the androgens, androstenedione and testosterone. These androgens are secreted into the extracellular fluid and diffuse across the basement membrane to the granulosa cells to provide precursors for estrogen production. In contrast to theca cells, granulosa cells express high levels of aromatase activity in response to FSH stimulation. Thus, these cells efficiently convert androgens to estrogens, primarily the potent estrogen, estradiol. In sum, ovarian steroidogenesis is dependent on the effects of LH and FSH acting independently on the theca cells and granulosa cells, respectively.

STEROIDOGENESIS ACROSS THE LIFE SPAN

Childhood

The human ovary has the capacity to produce estrogens by 8 weeks' gestation, however, a minimal amount of steroid is actually synthesized at any time during fetal development (Miller, 1988).

Circulating levels of the gonadotropins, LH and FSH, vary markedly at different ages of a woman's life. During the second trimester of fetal development, the plasma levels of gonadotropins rise to levels similar to those observed in menopause (Faiman, 1976). The fetal hypothalamic-pituitary axis continues to mature during the second trimester of pregnancy, becoming more sensitive to the high circulating levels of estrogen and progesterone secreted by the placenta (Kaplan, 1976; Yen, 1986). In response to the high levels of these steroids, fetal gonadotropins fall to low levels prior to birth. After delivery, gonadotropin levels rise abruptly in the neonate due to separation from the placenta and subsequent freedom from inhibition by placental steroids (Winter, 1976).

The elevated levels of gonadotropins in the newborn persist for the first few months of life, declining to low levels in early childhood

(Winter, 1976). There may be multiple etiologies for the low gonadotropin levels during this period of life. The hypothalamic-pituitary axis has been found to have increased sensitivity to negative feedback, even by the low circulating levels of gonadal steroids at this stage (Yen, 1986). There is growing evidence that there is an intrinsic role of the central nervous system in maintaining low gonadotropin levels. In support of this mechanism, low levels of LH and FSH are found in children with gonadal dysgenesis (Conte, 1975).

Puberty

One of the first signs of puberty is a sleep-associated increase in LH secretion (Fig. 15-22). Over time, increased gonadotropin secretion is noted throughout the day. An increased FSH:LH ratio is typical in the premenarchal girl and postmenopausal woman. During the reproductive years, LH exceeds FSH levels, reversing this ratio.

FIGURE 15-22

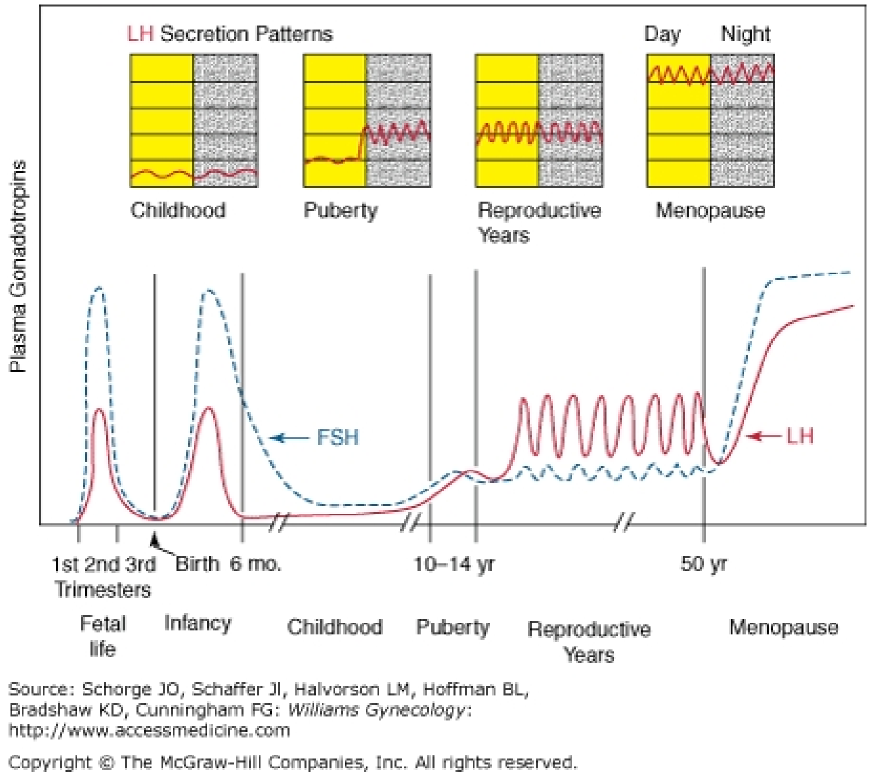


Diagram illustrates variations in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) during different life stages in the female. *(From Carr, 1998, with permission.)*

Increased gonadotropin levels stimulate ovarian estradiol production. The rise in estrogen levels results in the growth spurt, maturation of the female internal and external genitalia, and development of a female habitus including breast enlargement (thelarche). Activation of the pituitary-adrenal axis results in an increase in adrenal androgen production and the associated development of axillary and pubic hair (adrenache or pubarche). Increased gonadotropin levels ultimately lead to ovulation and subsequent menses, with the timing of the first menstrual period defining menarche. This developmental process takes approximately 3 to 4 years.

Postmenopause

The postmenopausal ovary contains only a few follicles, and as a result, plasma estrogen and inhibin levels decrease markedly after cessation of ovulatory cycles. Through loss of this negative feedback, LH and FSH levels are strikingly elevated in postmenopausal women. Elevated LH levels can stimulate production of C_{19} steroids (mainly androstenedione) in ovarian stromal cells. This ovarian-derived androstenedione as well as adrenal androgens can be converted by peripheral tissues to estrone, the principal

estrogen in the plasma of postmenopausal women. The major site for the conversion of androstenedione to estrone is adipose tissue. Peripheral conversion of circulating androstenedione to estrone is higher in postmenopausal women than in premenopausal women of a given body weight, and is directly correlated with body weight. These low circulating estrogen levels are usually inadequate to protect against bone loss.

Follicular Development

Follicular development begins with primordial follicles that were generated during fetal life (see Fig. 15-20). Each follicle consists of an oocyte arrested in the first meiotic division surrounded by a single layer of flattened granulosa cells. These follicles are separated from the stroma by a thin basement membrane. Pre-ovulatory follicles are avascular. As a result, they are critically dependent on diffusion, and later gap junctions, for obtaining nutrients and clearing metabolic waste. Diffusion also allows passage of steroid precursors from the thecal to the granulosa cell layer.

PRIMARY FOLLICLE

In the next stage of development, the granulosa cells become cuboidal and increase in number to form a pseudostratified layer. The follicle is now termed a *primary follicle* . Intercellular gap junctions develop between adjacent granulosa cells and between granulosa cells and the developing oocyte (Albertini, 1974). These gap junctions allow for the passage of nutrients, ions, and regulatory factors between cells. Gap junctions also allow cells without gonadotropin receptors to receive signals from cells with receptor expression (Fletcher, 1985). As a result, hormone-mediated effects can be transmitted throughout the follicle.

During this stage, the oocyte begins secretion of an acellular coat known as the zona pellucida. The human zona pellucida contains at least three proteins, named ZP1, ZP2, and ZP3. In current physiologic models, receptors on the acrosome head of the sperm recognize ZP3. This interaction results in release of acrosomal contents, penetration of the zona pellucida, and fertilization of the egg. Although the precise mechanism may differ between species, enzymes released from the acrosome induce alterations in ZP2, resulting in hardening of the coat. This process prevents fertilization of the oocyte by more than one sperm (Nixon, 2007).

SECONDARY FOLLICLE

Development of a secondary, or preantral, follicle includes final growth of the oocyte and a further increase in granulosa cell number. The stroma differentiates into the *theca interna* , which is adjacent to the basal lamina, and the *theca externa* , which abuts the surrounding stroma (Eppig, 1979).

TERTIARY FOLLICLE

With ongoing development, follicular fluid begins to collect between the granulosa cells, ultimately producing a fluid filled space known as the antrum. The follicle is now termed a *tertiary follicle* or *antral follicle* . Further accumulation of antral fluid results in a rapid increase in follicular size and development of a preovulatory follicle, also termed a *graafian follicle* .

Granulosa cells in the antral follicle are histologically and functionally divided into two groups. The granulosa cells surrounding the oocyte form the cumulus oophorus, whereas the granulosa cells surrounding the antrum are known as mural granulosa cells.

Antral fluid consists of a plasma filtrate and factors secreted by the granulosa cells. These locally produced factors, which include estrogen and growth factors, are present in substantially higher concentrations in follicular fluid than in the circulation and are likely critical for successful follicular maturation.

GONADOTROPINS AND FOLLICULAR DEVELOPMENT

Early stages of development (up to the secondary follicle) do not require gonadotropin stimulation and thus are said to be gonadotropin-independent. Final follicular maturation requires the presence of adequate amounts of circulating LH and FSH and is therefore said to be gonadotropin-dependent (Butt, 1970). Of note, data are beginning to accumulate that suggest that progression from gonadotropin-independent to gonadotropin-dependent stages is not as abrupt as was previously believed.

CONCEPT OF A SELECTION WINDOW

Follicular development is a multi-step process, which proceeds over at least 3 months, culminating in ovulation from a single follicle. Each month a group of follicles, known as a cohort, begins a phase of semi-synchronous growth. The size of this cohort

appears to be proportional to the number of inactive primordial follicles within the ovaries and has been estimated at three to eleven follicles per ovary in young women (Gougeon, 1994; Hodgen, 1982; Pache, 1990).

It is important to emphasize that the ovulatory follicle is recruited from a cohort that began development two to three cycles prior to the ovulatory cycle. During this time, most follicles will die, as they will not be at an appropriate stage of development during the selection window.

During the luteal-follicular transition, a small increase in FSH levels is responsible for selection of the single dominant follicle that will ultimately ovulate (Schipper, 1998). As previously described, theca cells produce androgens and granulosa cells generate estrogens. Estrogens increase with increased follicular size, enhance the effects of FSH on granulosa cells, and create a feed-forward action on follicles that produce estrogens.

It has also been suggested that the intrafollicular levels of members of the insulin-like growth factor family (IGFs) may synergize with FSH to help select the dominant follicle. Of note, the ovary expresses the potent angiogenic factor, vascular endothelial growth factor (VEGF). Studies have demonstrated elevated levels of VEGF around the follicle that will be selected. This follicle would presumably be exposed to higher levels of circulating factors such as FSH. Conversely, follicles that will undergo atresia have a limited blood supply, presumably due to decreased VEGF expression, which effectively decreases delivery of circulating factors to the follicles (Ravindranath, 1992.)

Granulosa cells also produce inhibin B, which passes from the follicle into the plasma and specifically inhibits the release of FSH, but not of LH, by the anterior pituitary. The combined production of estradiol and inhibin B by the dominant follicle results in the decline of follicular phase FSH levels, and at least in part, may be responsible for the failure of other follicles to reach preovulatory status during any one cycle.

ESTROGEN-DOMINANT FOLLICULAR MICROENVIRONMENT

Ongoing follicular maturation requires the successful conversion from an androgen-dominant microenvironment to an estrogen-dominant microenvironment. At low concentrations, androgens stimulate aromatization and contribute to estrogen production. However, intrafollicular androgen levels will rise if aromatization in the granulosa cells lags behind androgen production by the thecal layer. At higher concentrations, androgens are converted to the more potent 5α-androgens, such as dihydrotestosterone. These androgens inhibit aromatase activity, cannot be aromatized to estrogens, and inhibit FSH induction of LH-receptor expression on the granulosa cells (Hillier, 1980; Jia, 1985; McNatty, 1979b).

This model predicts that follicles that lack adequate FSH receptor and granulosa cell number will remain primarily androgenic and will therefore become atretic. In support of this model, an increased androgen:estrogen ratio is found in the follicular fluid of atretic follicles and a number of studies have demonstrated that high estrogen levels prevent apoptosis.

Insulin-like growth factor also has apoptosis-suppressing activity, and is produced by granulosa cells. This action of IGF-I is suppressed by certain IGF-binding proteins that are present in the follicular fluid of atretic follicles. The action of FSH to prevent atresia may therefore result, in part, from its ability to stimulate IGF-I synthesis and suppress the synthesis of the IGF-binding proteins.

Follicular Phase

During the end of a previous cycle, estrogen, progesterone, and inhibin levels decrease abruptly. This is followed by a corresponding increase in circulating FSH levels (Fig. 15-23) (Hodgen, 1982). As just described, this increase in FSH level is responsible for recruitment of the follicle cohort that contains the follicle destined for ovulation. Despite general belief, sonographic studies in women have demonstrated that ovulation does not alternate sides, but occurs randomly from either ovary (Baird, 1987).

FIGURE 15-23

Graphs display gonadotropin, inhibin, and sex-steroid level changes during a normal menstrual cycle. In the first graph, peaking of luteinizing hormone (LH) (red line) and follicle-stimulating hormone (FSH) (blue line) levels are displayed. In the middle graph, changing levels of inhibin A and inhibin B levels are shown. Note that inhibin B levels (solid green line) peak temporally near the midcycle surge in the LH level, whereas maximal elevation of inhibin A (orange line) occurs several days following this peak. In the third graph, elevations in estradiol levels (pink line) are noted prior to the surge in LH levels and in the midluteal phase. Progesterone levels (purple line) peak in the midluteal phase. E_2 = estradiol; P_4 = progesterone.

In women with waning ovarian function, the FSH level at this time of the cycle is elevated relative to that of younger women, presumably due to a loss of ovarian inhibin production. As a result, measurement of an early follicular or cycle day-3 estradiol level is frequently obtained in infertility clinics. The accelerated increase in serum FSH levels results in more robust recruitment of follicles and may explain both the shortened follicular phase observed in these women and the increased incidence of spontaneous twins.

During the midfollicular phase, follicles produce increased amounts of estrogen and inhibin, resulting in a decline in FSH levels through negative feedback. This drop in FSH levels is believed to contribute to selection of the follicle destined to ovulate, termed the *dominant follicle* . Based on this theory, remaining follicles express decreased numbers of FSH receptors and therefore are unable to respond adequately to declining FSH levels. Also of note, the ovary expresses the potent angiogenic factor, VEGF.

During most of follicular development, granulosa cell responses to FSH stimulation include an increase in granulosa cell number, an

increase in aromatase expression, and in the presence of estradiol, expression of LH receptors on the granulosa cells. With the development of LH-receptor expression during the late follicular phase, granulosa cells begin to produce small amounts of progesterone. This progesterone decreases granulosa cell proliferation, thereby slowing follicular growth (Chaffkin, 1992). Progesterone is primarily responsible for generating the FSH surge (Erickson, 1979; McNatty, 1979a). Progesterone also augments the positive feedback of estrogen as discussed in the following section (Couzinet, 1992). This latter effect may explain the occasional induction of ovulation in anovulatory, amenorrheic women when given progesterone to induce menses.

Ovulation and the Luteinizing Hormone Surge

Ovulation, the process by which the oocyte-cumulus is released from the follicle, has been compared with an inflammatory response. As such, products induced by these signaling cascades include gene products that rupture the follicle and remodel the follicular remnant into a corpus luteum.

Toward the end of the follicular phase, estradiol levels increase dramatically. For reasons that are not completely understood, with this rapid increase, estradiol is no longer inhibitory and instead develops positive feedback effects at both the hypothalamus and anterior pituitary gland to generate the LH surge. Estradiol concentrations of 200 pg/mL for 50 hours are necessary to initiate a gonadotropin surge (Young, 1976).

The LH surge acts rapidly on both the granulosa and theca cells of the preovulatory follicle to terminate the genes involved in follicular expression, while at the same time turning on the expression of genes required for ovulation and luteinization. In addition, the LH surge initiates the re-entry of the oocyte into meiosis, expansion of the cumulus oophorus, synthesis of prostaglandins, and luteinization of granulosa cells. The mean duration of the LH surge is 48 hours with ovulation occurring approximately 36 to 40 hours after the onset of the LH surge (Hoff, 1983; Lemarchand-Beraud, 1982). Abrupt termination of the surge is postulated to be due to acutely increasing steroid and inhibin secretion by the corpus luteum.

The granulosa cells surrounding the oocyte differ from mural granulosa cells in that they do not express LH receptors or synthesize progesterone. Cumulus oophorus granulosa cells develop tight gap junctions between each other and with the oocyte. The cumulus mass that accompanies the ovulating oocyte is believed to be important for providing a rough surface and increased size to improve oocyte "pick up" by the tubal fimbria. This surrounding cell mass may also be important for oocyte health.

Discordant oocyte maturation and luteinization is prevented by the action of locally produced factors, including oocyte maturation inhibitor (OMI) and luteinization inhibitor. Endothelin-1 has been proposed to be the luteinization inhibitor, whereas the identity of the OMI is under active investigation (Tedeschi, 1992). Intrafollicular activin may also help to prevent premature luteinization, as it suppresses progesterone production by granulosa cells (Li, 1992).

Recently, members of an epidermal growth factorâ€"like family, that is, amphiregulin, epiregulin, and beta-cellulin, were found to substitute for both the morphologic and biochemical events triggered by LH, including both expansion of the cumulus and maturation of the oocyte. Thus, these growth factors are part of the downstream cascade that begins with LH binding to its receptor and ends with ovulation.

Based on sonographic surveillance, extrusion of the oocyte only lasts a few minutes (Knobil, 1994). The exact mechanism of this expulsion is poorly defined, but is not due to an increase in follicular pressure (Espey, 1974). The presence of proteolytic enzymes in the follicle, including plasmin and collagenase, suggest that these enzymes are responsible for follicular wall thinning (Beers, 1975). The pre-ovulatory gonadotropin surge stimulates expression of tissue plasminogen activator by the granulosa and theca cells. The surge also decreases expression of plasminogen inhibitor, resulting in a marked increase in plasminogen activity (Piquette, 1993).

Prostaglandins also reach a peak concentration in follicular fluid during the pre-ovulatory gonadotropin surge (Lumsden, 1986). Prostaglandins may stimulate smooth muscle contraction in the ovary, thereby contributing to ovulation (Yoshimura, 1987). Women undergoing infertility treatment are advised to avoid prostaglandin synthetase inhibitors in the pre-ovulatory period to avoid luteinized unruptured follicle syndrome (LUFS) (Priddy, 1990; Smith, 1996). The incidence of LUFS has been estimated at 4.5 percent in cycling women. Significant controversy, however, exists about whether LUFS should be considered pathologic or simply a sporadic event (Kerin, 1983).

Luteal Phase

Following ovulation, the remaining follicular cells left by the ovulated follicle differentiate into the corpus luteum, literally meaning *yellow body* (Corner, 1956). This process, which requires LH stimulation, includes both morphologic and functional changes known as luteinization. The granulosa and theca cells proliferate and undergo hypertrophy to form granulosa-lutein cells and smaller theca-lutein cells, respectively (Patton, 1991). The conversion of a granulosa cell into a large luteal cell is a dramatic example of cellular differentiation.

During corpus luteum formation, the basement membrane that separates granulosa cells from theca cells degenerates and allows vascularization of previously avascular granulosa cells. Capillary invasion begins 2 days after ovulation, reaching the center of the corpus luteum by the fourth day. This increase in perfusion provides these luteal cells with access to circulating low-density lipoprotein (LDL), which is used to provide precursor cholesterol for steroid biosynthesis. This marked increase in blood supply can have clinical implications, as pain from a hemorrhagic corpus luteum cyst is a relatively frequent presentation to emergency rooms.

As might be predicted by its name, steroidogenesis in the corpus luteum is under the primary control of luteinizing hormone from the anterior pituitary gland. Based on its steroidogenic products, the luteal phase is considered progesterone dominant, in contrast to the estrogen dominance of the follicular phase. Increased vascularization, cellular hypertrophy, and an increased number of intracellular organelles transform the corpus luteum into the most active steroidogenic tissue in the body. Maximal levels of progesterone production are observed in the midluteal phase and have been estimated at an impressive 40 mg of progesterone per day. Ovulation can be safely assumed to have occurred if the progesterone level exceeds 3 ng/mL on cycle day 21. A progesterone level greater than 10 to 15 ng/mL generally indicates adequate luteal function and no need for progesterone supplementation in infertile women.

Although progesterone is the most abundant ovarian steroid during the luteal phase, estradiol is also produced in significant quantities. Estradiol levels drop transiently immediately after the LH surge and are followed by a steady increase to reach a maximum during the midluteal phase. The reason for this decrease is not known, but may result from direct inhibition of granulosa cell growth by increasing progesterone levels (Hoff, 1983).

The corpus luteum also produces large quantities of the polypeptide inhibin A. This coincides with a decrease in circulating FSH levels in the luteal phase. If inhibin A levels decline at the end of the luteal phase, FSH levels rise once more to begin selection of a oocyte cohort for the next menstrual cycle.

Gonadotropins and Luteal Function

Normal hormonal function of the corpus luteum depends on adequate serum LH levels, the presence of LH receptors on the luteal cells, and a sufficient number of luteal cells (Vande Wiele, 1970). As a result, it is critical that LH receptor expression on the granulosa cells was appropriately induced during the prior follicular phase. In support of the importance of this hormone for survival of the corpus luteum, it has been demonstrated that blunted serum LH concentrations are correlated with a reduced luteal phase length.

Luteal function is further influenced by gonadotropin levels during the preceding follicular phase. A reduction in LH or FSH secretion is correlated with poor luteal function (McNeely, 1988; Stouffer, 1980). Presumably, a lack of FSH leads to a decrease in the total number of granulosa cells. Furthermore, luteal cells in these suboptimal cycles will have a decreased number of FSH-induced LH receptors and thus will be less responsive to LH stimulation.

Luteolysis

If pregnancy does not occur, the corpus luteum regresses through a process called *luteolysis* . The mechanism for luteolysis is poorly understood, but luteal regression is presumed to be tightly regulated and luteal cycle length varies minimally. Following luteolysis, the blood supply to the corpus luteum diminishes, and progesterone and estrogen secretion drop precipitously. Luteal cells undergo apoptosis and become fibrotic, creating the *corpus albicans* (white body).

If pregnancy occurs, human chorionic gonadotropin (hCG) produced by the early gestation "rescues" the corpus luteum from atresia by binding to and activating the LH receptor on luteal cells. Corpus luteum steroidogenesis, stimulated by hCG, maintains

endometrial stability until placental steroid production is adequate to assume this function late in the first trimester. For this reason, surgical removal of the corpus luteum during pregnancy should be followed by progesterone replacement until approximately 10 weeks' gestation.

Gonadal Peptides

ACTIVIN-INHIBIN-FOLLISTATIN SYSTEM

Ovaries synthesize and secrete a group of peptide factorsâ€”inhibin, activin, and follistatin. Circulating inhibin is believed to be primarily gonadal in origin, as serum levels drop abruptly after castration (Demura, 1993).

Serum inhibin levels vary widely across the menstrual cycle (Groome, 1996; McLachlan, 1987). An inverse relationship between circulating inhibin levels and FSH secretion is seen and is consistent with a negative feedback role for inhibin in regulating FSH secretion. During the early follicular phase, FSH stimulates the secretion of inhibin B by the granulosa cells (Buckler, 1989) (see Fig. 15-23). However, increasing levels of circulating inhibin B blunt FSH secretion later in the follicular phase. During the luteal phase, regulation of inhibin production comes under the control of LH and switches from inhibin B to inhibin A (McLachlan, 1989). Inhibin levels peak during the midluteal phase, decrease with the loss of luteal function, and remain low during the luteal-follicular transition and early follicular phase.

Serum levels of activin, although detectable, are low and remain stable across the menstrual cycle (Demura, 1993). Follistatin levels likewise are unchanged across the reproductive cycle. Furthermore, circulating follistatin levels are similar in GnRH-deficient and postmenopausal women as well as women following oophorectomy (Kettel, 1996; Khoury, 1995). These data strongly suggest that circulating follistatin is not derived from the ovary, although its source remains unknown. Essentially all follistatin is bound to activin throughout the menstrual cycle (McConnell, 1998). Therefore, although the ovary does produce both activin and follistatin, these factors appear to act locally rather than modulate gonadotrope function.

INSULIN-LIKE GROWTH FACTOR (IGF)

The relative roles of IGF-I and IGF-II in mediating ovarian function may differ across species, but current data suggest that IGF-II is more important in the human (el Roeiy, 1993). Gonadotropins stimulate IGF-II production in theca cells, granulosa cells, and luteinized granulosa cells. Insulin-like growth factor receptors are expressed on the theca and granulosa cells, supporting an autocrine/paracrine action in the follicle (Hernandez, 1992). Follicle-stimulating hormone also mediates expression of IGF-binding proteins (IGF-BPs). This system, although complex, allows additional fine-tuning of intrafollicular activity (Adashi, 1991; Thierry van Dessel, 1996).

ENDOMETRIUM

Histologic Menstrual Cycle Changes

The endometrium consists of two layers: the *basalis layer,* which lies against the myometrium, and the *functionalis layer,* which is apposed to the uterine lumen. The basalis layer, which does not change significantly across the menstrual cycle, is critical for regeneration of the endometrium following menstrual sloughing. The functionalis layer of the endometrium can be further divided into the superficial, thin, *stratum compactum,* which consists of gland necks and dense stroma, and the underlying *stratum spongiosum,* which contains glands and large amounts of loosely organized stroma and interstitial tissue.

After menstruation, the endometrium is only one to two millimeters thick. Under the influence of estrogen, the glandular and stromal cells of the functionalis layer proliferate rapidly following menses (Fig. 15-24). This period of rapid growth, termed the *proliferative phase,* corresponds to the ovary's follicular phase. As this phase progresses, glands become more tortuous and cells lining the glandular lumen undergo pseudostratification. The stroma remains compact. Endometrial thickness is about 12 millimeters at the time of the LH surge and does not increase significantly thereafter.

Following ovulation, the endometrium transforms into a secretory tissue. The period during and after transformation is defined as the *secretory phase* of the endometrium and correlates to the ovary's *luteal phase* . Glycogen-rich subnuclear vacuoles appear in cells lining the glands. Under further stimulation by progesterone, these vacuoles move from the glandular base toward the lumen and expel their contents. This secretory process peaks on approximately postovulatory day 6, coinciding with the day of implantation. Throughout the luteal phase, glands become increasingly tortuous, and the stroma becomes more edematous. In addition, spiral arteries that feed the endometrium increase their number and coiling.

If a blastocyst does not implant, then the corpus luteum is not maintained by placental hCG, progesterone levels drop, and endometrial glands begin to collapse. Polymorphonuclear leukocytes and monocytes from the nearby vasculature infiltrate the endometrium. The spiral arteries constrict leading to local ischemia, and lysosomes release proteolytic enzymes that accelerate tissue destruction. Prostaglandins (PGs), particularly prostaglandin F_2 , are present in the endometrium and likely contribute to arteriolar vasospasm. Prostaglandin F_2 also induces myometrial contractions, which may aid in expelling the endometrial tissue.

The entire endometrial functionalis layer is thought to exfoliate with menstruation, leaving only the basalis layer to provide cells for endometrial regeneration. However, in a number of reports, investigators have found large variations in the amount of tissue shed from different levels of the endometrium. Following menstruation, re-epithelialization of the desquamated endometrium is believed to be initiated within 2 to 3 days after the onset of menses and to be completed within 48 hours.

Regulation of Endometrial Tissue Degradation and Hemorrhage

Within the endometrium, a large number of proteins maintain a delicate balance between tissue integrity and the localized tissue destruction required for menstrual sloughing or for trophoblast invasion during implantation. Genes encoding these tissue proteins are believed to be regulated by cytokines, growth factors, and steroid hormones, although the details of this regulation are still incomplete.

Of these tissue proteins, tissue factor (TF) is a membrane- associated protein that activates the coagulation cascade on contact with blood. In addition, urokinase and tissue plasminogen activator (TPA) are both fibrinolytic, increasing the conversion of plasminogen to plasmin and activating tissue breakdown. TPA activity is blocked by plasminogen activator inhibitor-1 (PAI-1), also present in the endometrial stroma (Lockwood, 1993; Schatz, 1995). Importantly, matrix metalloproteinases (MMPs) are a family of enzymes with overlapping substrate specificities for collagens and other extracellular matrix components. The composition of the MMPs vary within the different endometrial tissues and during the menstrual cycle. Endogenous MMP inhibitors, called tissue inhibitors of matrix metalloproteinases (TIMPs), are also increased premenstrually and limit MMP degradative activity.

Endometrial Factors that Stimulate Vasoconstriction and Myometrial Contractility

Effective menstruation depends on appropriately timed endometrial vasoconstriction and myometrial contraction. Vasoconstriction produces ischemia, which leads to endometrial damage and subsequent menstrual sloughing. Within the endometrium, epithelial and stromal cells secrete endothelin-1, a member of a family of potent vasoconstrictors. Enkephalinase, which degrades endothelins, is expressed at its highest levels in the midsecretory endometrium (Head, 1993). However, in the late luteal phase, drops in serum progesterone levels lead to a loss of enkephalinase expression. This permits increased endothelin activity, which in turn provides a physiologic system inclined towards vasoconstriction.

In concert with endometrial sloughing, myometrial contractions control blood loss by compressing endometrial vasculature and expelling menstrual discharge.

A fall in serum progesterone decreases an enzyme that degrades prostaglandins. This allows increasing PGF_2 activity in the myometrium and triggers myometrial contractions (Casey, 1980).

Uterine Effects of Estrogens and Progestins

The expression of estrogen receptors and progesterone receptors in the endometrium is highly regulated across the menstrual cycle. This regulation of steroid receptor number provides an additional mechanism for controlling steroid effects on endometrial development and function.

Estrogen receptors are expressed in the nuclei of epithelial, stromal, and myometrial cells, and a peak concentration is seen during the proliferative phase. However, during the luteal phase, rising progesterone levels decrease estrogen receptor expression (Lessey, 1988).

Endometrial progesterone receptors peak at midcycle in response to rising estrogen levels. By midluteal phase, progesterone receptor expression in the endometrium is nearly absent, although expression remains strong in the stromal compartment (Lessey, 1988; Press, 1988).

The proliferation and differentiation of the uterine epithelium is under the control of estradiol, progesterone, and various growth factors. The importance of estrogens for endometrial development is emphasized by the documented increase in endometrial hyperplasia in women receiving unopposed estrogen therapy. Estrogen exerts its effects directly, through interaction with estrogen receptors and through induction of various growth factors including IGF-1, TGF-α, and epidermal growth factor (EGF) (Beato, 1989; Dickson, 1987). The effects of progesterone on endometrial growth vary among endometrial layers. Progesterone is clearly critical for the conversion of the functionalis layer from a proliferative to a secretory pattern. Moreover, progesterones also appear to promote cellular proliferation in the basalis layer.

Growth Factors and Cell Adhesion Molecules

A large number of growth factors and associated receptors have been identified in the endometrium (Table 15-7). Each of these factors has its own pattern of expression, and this complexity has made it difficult to determine which of the factors is most critical for endometrial function (Ohlsson, 1989; Sharkey, 1995).

Table 15-7 Endometrial Growth Factors and Their Function

Growth Factors	Suggested Function	Production Site
Transforming growth factor-β (TGF-β) family	Regulates extracellular matrix organization through regulation of TIMPs and PAI-1	Epithelial and stromal cells
Epidermal growth factor (EGF)	Stimulates stromal cell differentiation, regulates endometrial cell expression of integrins	Stromal and glandular cells
Insulin-like growth factors (IGF-I and IGF-II)	Promotes mitosis and differentiation in the endometrium	Endometrium, ovary, trophoblasts
IGF binding protein-1 (IGFBP-1)	Modulates trophoblast invasion	Decidualized stromal cells
Platelet-derived growth factor (PDGF)	Promotes angiogenesis, stimulates stromal cell proliferation	Stromal cells, activated platelets
Vascular endothelial growth factor (VEGF)	Modulates angiogenesis and vascular permeability	Glandular cells
Tumor necrosis factor-β (TNF-β)	Promotes mitogenic, angiogenic, inflammatory, and immunomodulatory effects	Endometrium, trophoblasts
Macrophage colony-stimulating factor (MCSF)	Stimulates monocyte maturation, regulates mature macrophage cell function	Endometrium, decidua, placenta
Leukemia inhibitory factor (LIF)	Promotes blastocyst implantation	Endometrium, blastocyst, placenta

PAI-1 = plasminogen activator inhibitor-1; TIMP = tissue inhibitor of matrix metalloproteinase.

In addition to growth factors, cell adhesion molecules found within the endometrium play an important role in endometrial function. These molecules fall into four classes: the integrins, the cadherins, the selectins, and members of the immunoglobulin superfamily. Each has been implicated in endometrial regeneration and embryo implantation (Coutifaris, 1997).

Implantation Window

In the human, the embryo enters the uterine cavity 2 to 3 days after fertilization with implantation beginning approximately 4 days later (Fig. 15-25). Studies in humans and animal models have demonstrated that normal implantation and embryonic development require synchronous development of the endometrium and the embryo (Pope, 1988). The human blastocyst may have less stringent requirements for implantation than other species, as ectopic implantation occurs relatively frequently.

Uterine receptivity can be defined as the temporal window of endometrial maturation during which trophectoderm attaches to the endometrial epithelial cells with subsequent invasion of the endometrial stroma. Based on a number of studies, the window of implantation in the human is relatively broad, extending from day 20 through day 24 of the menstrual cycle. Determination of this temporal window is critical, as only those factors expressed during this time can be considered putative markers or functional mediators of uterine receptivity.

Several investigators have attempted to correlate biochemical markers and ultrastructural features of the endometrium with the presence of uterine receptivity. Endometrial maturation is associated with loss of both surface microvilli and ciliated cells, as well as the development of cellular protrusions, called *pinopods,* on the apical surface of the endometrium. Specifically, the presence of

pinopods is considered to be an important morphologic marker of peri-implantation endometrium. Pinopod formation is known to be highly progesterone dependent (Yoshinaga, 1989).

Biochemical markers of uterine receptivity have included studies of mucin 1 (MUC1) and keratin sulfate. These transmembrane glycoproteins are significantly increased on the glandular cell surface during the peri-implantation period (Aoki, 1989). Integrins are also an intriguing putative marker for identification of the implantation window (Sueoka, 1997). However, to date no single integrin molecule has been determined to be the critical marker for identification of the implantation window.

Endometrial Dating and Luteal Phase Defect

In a classic study, Noyes and colleagues (1950) described a system for correlating the endometrial histologic appearance with menstrual cycle phase. With their system, a discrepancy of more than 2 days, termed a *luteal phase defect,* was linked to implantation failure and early pregnancy loss (Olive, 1991). Clinicians have traditionally chosen postovulatory days 10 to 12 of the menstrual cycle to obtain an endometrial biopsy. However, subsequent studies have suggested that endometrial sampling at the time of implantation (postovulation day 6) may be more accurate. Women diagnosed with luteal phase defects are typically treated with progesterone supplementation using natural progesterone products.

With time, it has become clear that there are multiple problems associated with endometrial dating. First, interpretation of the endometrial biopsies carries large intra- and interobserver variation. Second, the predictive value for an out-of-phase biopsy has proven to be lower than initially believed. Finally, it is unclear that progesterone supplementation improves pregnancy outcome. As a result, the endometrial biopsy has fallen from favor as an endometrial dating tool. However, as characterization of endometrial factors required for normal implantation moves forward, ultimately it may be possible to immunostain endometrial biopsy sections for these factors. This may produce more accurate biopsy interpretation.

ENDOCRINOLOGY OF PREGNANCY

Extensive endocrine changes occur in the maternal circulation during pregnancy because of altered maternal physiology as well as contributions by the placenta and fetus. A more detailed discussion of these changes can be found in *Williams Obstetrics,* 22nd edition (Cunningham, 2005).

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is produced by placental trophoblasts and can be detected in serum as early as 7 to 9 days after the LH surge. Levels of hCG increase rapidly in early pregnancy, doubling approximately every 2 days. Levels of this peptide hormone peak at approximately 100,000 mIU/mL during the first trimester of pregnancy. This is followed by a relatively sharp decrease in the early second trimester and maintenance at lower levels throughout the remainder of pregnancy.

As noted earlier, hCG binds to LH/CG receptors on corpus luteum cells and stimulates steroidogenesis in the ovary. This peptide hormone is critical for corpus luteum steroid production during early pregnancy before the placenta attains adequate steroidogenic capability to maintain endometrial integrity and uterine quiescence. The transfer in production of estrogens and progesterone from the ovary to the placenta is often called the "luteal-placental shift".

As the placenta is the primary source for hCG production, measurement of plasma hCG levels has proven to be an effective screening tool for pregnancies with altered placental mass or function. Relatively elevated levels of hCG are observed with mutifetal gestation or a fetus with Down syndrome. Lower hCG levels are observed in cases of poor placentation, as occurs in ectopic pregnancy or spontaneous miscarriage. Serial hCG measurements can be very helpful to monitor these latter conditions, as the doubling time is relatively reliable (see Chap. 7, Serum β-HCG Measurements).

Markedly abnormal elevations in hCG levels are most often observed in the presence of gestational trophoblastic disease, including hydatidiform mole and choriocarcinoma (see Chap. 37). As noted previously, hCG and thyroid-stimulating hormone (TSH) share a common α-subunit and related β-subunits. Due to this structural similarity, hCG can bind to and activate TSH receptors in the thyroid gland, explaining the association of molar pregnancy with hyperthyroidism.

In addition, hCG can be a useful tumor marker for nontrophoblastic neoplasias. Ectopic (nonplacental) production of hCG, either the intact dimer or the α-subunit, is frequently associated with germ cell tumors and has been reported for a variety of tumors

arising from the mucosal epithelium of the cervix, bladder, lung, and nasopharynx (see Chap. 36, Laboratory Testing). It has been postulated that hCG inhibits apoptosis in these tumors, thereby allowing rapid growth (Iles, 2007).

Hypothalamic and Pituitary Peptide Hormones

The placenta produces a remarkable number of peptide hormones. Many of these are more commonly thought of as hypothalamic or pituitary in origin. For example, the placenta secretes thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), growth hormoneâ€œreleasing hormone (GHRH), and somatostatin. Pituitary-like peptides include human chorionic gonadotropin (hCG), adrenocorticotropin hormone (ACTH), human placental lactogen (hPL), and human growth hormone variant (hGH-v). The placenta also is notable for its production of inhibins, activins, relaxin, and atrial natriuretic peptide.

Placental Steroids

LUTEAL-PLACENTAL SHIFT

The corpus luteum is the major source of steroid production in early pregnancy. By the seventh week of gestation, approximately 50 percent of estrogen in the maternal circulation is produced in the placenta (Siiteri, 1966). Removal of the corpus luteum will result in miscarriage before the switch to placental steroid production. Using a conservative approach, progesterone supplementation should be considered in any woman who has surgical removal of the corpus luteum before 10 weeks of gestation, with supplementation continued at least to this time (see Chap. 6, Maternal Surgery).

PROGESTERONE

Placental progesterone is synthesized from cholesterol primarily derived from maternal circulation. Cholesterol is initially converted to pregnenolone, which next is converted to progesterone by 3β-hydroxysteroid dehydrogenase. Progesterone is secreted continuously into the maternal circulation rather than stored, as occurs for peptide products. Maternal progesterone serum levels increase from approximately 25 ng/mL during the midluteal phase to 150 ng/mL at term. Progesterone has been postulated to be the critical mediator of uterine quiescence during pregnancy, possibly via inhibition of prostaglandin synthesis. Progesterone is also a potent immunomodulatory agent that may block immune rejection of the developing fetus.

ESTRIOL

The placenta lacks the steroidogenic enzyme CYP17, which is required for converting C21 steroids, including progesterone, into C19 androgens. Therefore, placental estrogen production is dependent on precursors provided by other systems. While progesterone production is dependent on maternal precursors, estrogen production is dependent on precursors from the fetal adrenal gland.

The fetal adrenal gland is nearly as large as the fetal kidney, and therefore is proportionally enlarged relative to the adult adrenal gland. The fetal adrenal cortex produces DHEAS, which is subsequently hydroxylated to form 16α-hydroxy-DHEAS in the fetal liver. The high levels of aromatase activity in the placenta convert 16α-hydroxy-DHEAS to estriol, explaining the high circulating levels of this steroid during pregnancy (Siiteri, 1966). As with progesterone, most placental estrogen enters the maternal compartment.

Estriol is considered the "pregnancy estrogen", as it is only expressed at high levels at this time. Nevertheless, it should be appreciated that the more potent estrogen, estradiol, is produced in equal or slightly higher concentrations and may be responsible for observed estrogenic effects.

STEROID PRODUCTION RELATED TO FETAL WELL BEING

It has been appreciated for many decades that measurement of urinary estriol can be used as a marker for fetal health. Estrogen levels are markedly blunted in patients making low levels of androgen precursors, such as occurs in anencephaly, adrenal hypoplasia, or fetal demise. Serum estriol is now used in the second trimester as part of the triple screen and quadruple screen to look for Down syndrome and neural-tube defects, among other fetal anomalies.

AMENORRHEA: INTRODUCTION

Evaluation and management of a patient with amenorrhea is a common practice in gynecology, and the prevalence of pathologic amenorrhea ranges from 3 to 4 percent in reproductive-aged populations (Bachmann, 1982; Pettersson, 1973). Amenorrhea is diagnosed in a female who has not menstruated: (1) by age 13 years and who lacks other evidence of pubertal development; (2) by age 15, even in the presence of other pubertal signs; or (3) for a length of time equivalent to a total of three previous cycle intervals or 6 months. Although amenorrhea has classically been defined as *primary* (no prior menses) or *secondary* (cessation of menses), this distinction may lead to diagnostic error and should be avoided.

In some circumstances, it is reasonable to initiate an evaluation despite the absence of these strict criteria. Examples include a patient with the stigmata of Turner syndrome, obvious virilization, or a history of uterine curettage. An evaluation for delayed puberty should also be considered before the ages listed if a patient or her parents are concerned.

Although the list of possible etiologies is extensive, most causes will fall into a limited number of categories (Tables 16-1 and 16-2). Of course, amenorrhea is a normal state prior to puberty, during pregnancy and lactation, and following the menopause.

Table 16-1 Primary Amenorrhea: Frequency of Etiologies

Presentation	Frequency (%)
Hypergonadotropic hypogonadism	43
45,X and variants	27
46,XX	14
46,XY	2
Eugonadism	30
MÃ¼llerian agenesis	15

NORMAL MENSTRUAL CYCLE

A differential diagnosis for amenorrhea can be developed based on requirements for normal menses. Generation of a cyclic, controlled pattern of uterine bleeding requires precise temporal and quantitative regulation of a number of reproductive hormones.

First, the hypothalamic-pituitary-ovarian axis must be functional. The hypothalamus releases pulses of gonadotropin-releasing hormone (GnRH) into the portal circulation at defined frequencies and amplitude. Gonadotropin-releasing hormone stimulates the synthesis and secretion of the gonadotropins, that is, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), by the gonadotrope cells of the anterior pituitary gland. These gonadotropins enter the peripheral circulation and act on the ovary to stimulate both follicular development and ovarian hormone production. These ovarian hormones include the steroid hormones (estrogen, progesterone, and androgens), as well as the peptide hormone inhibin. As suggested by its name, inhibin blocks FSH synthesis and secretion. Gonadal steroids are inhibitory in both the pituitary and the hypothalamus. Development of a mature follicle results in a rapid rise in estrogen levels, which acts positively at the pituitary to generate a surge in LH release. The mechanism by which this previously negative estrogen feedback switches to positive feedback is unknown. In addition to LH release, circulating estrogens stimulate the development of a thickened, proliferative, endometrial lining.

Following ovulation, LH stimulates luteinization of the follicular granulosa cells and surrounding theca with the formation of the corpus luteum. The corpus luteum continues to produce estrogen, but also secretes high levels of progesterone. Progesterone converts the endometrium to a secretory pattern. If pregnancy occurs, the corpus luteum is "rescued" by human chorionic gonadotropin (hCG) secreted from early trophoblastic cells. If pregnancy does not occur, then progesterone and estrogen secretion ceases, the corpus luteum regresses, and endometrial sloughing ensues. The pattern of this "progesterone withdrawal bleed" will vary in duration and blood loss between women, but should be relatively constant across cycles for each individual.

Menses can be absent even in the presence of normal cyclic hormonal changes due to the presence of anatomic abnormalities. The endometrium must be able to respond normally to hormonal stimulation, and the cervix, vagina, and introitus must be present and patent.

CLASSIFICATION SYSTEM

Numerous classification systems for the diagnosis of amenorrhea have been developed, and all have their strengths and weaknesses. One useful scheme is outlined in Table 16-3. This system divides the causes of amenorrhea into anatomic versus hormonal etiologies with further division into inherited versus acquired disorders.

As described above, normal menses requires adequate ovarian production of steroid hormones. Decreased ovarian function (hypogonadism) may result either from a lack of stimulation by the gonadotropins (*hypo* gonadotropic hypogonadism) or from primary failure of the ovary (*hyper* gonadotropic hypogonadism) (Table 16-4).

ANATOMIC DISORDERS

Anatomic abnormalities that may present as amenorrhea can broadly be viewed as either inherited or acquired disorders of the outflow tract (uterus, cervix, vagina, and introitus) (see Chap. 18, Description and Patient Presentation).

Inherited

These are a frequent cause of amenorrhea in adolescents, and pelvic anatomy is abnormal in approximately 15 percent of women with primary amenorrhea (American Society for Reproductive Medicine, 2006). Figure 16-1 depicts the range of anatomic defects that may present with amenorrhea.

FIGURE 16-1

OUTFLOW TRACT OBSTRUCTION

Beginning at the caudal end of the female genital tract, labial agglutination or fusion is often associated with disorders of sexual development, particularly female pseudohermaphroditism due to excess androgen exposure of a 46,XX female fetus in utero. These androgens may be due to fetal congenital adrenal hyperplasia (CAH) or may be derived from maternal circulation, such as develops with a luteoma of pregnancy.

Amenorrhea will be observed in the presence of an imperforate hymen (1 in 2,000 women), a transverse vaginal septum (1 in 70,000 women), or isolated atresia of the vagina or cervix (see Figs. 18-5 and 18-10) (Banerjee, 1999; Parazzini, 1990; Reid, 2000). Patients with these anomalies have a 46,XX karyotype, female secondary sexual characteristics, and normal ovarian function. Therefore, the amount of uterine bleeding is normal, but its typical path for egress is obstructed or absent. These patients may note moliminal symptoms, such as breast tenderness, food cravings, and mood changes, which are attributable to elevated progesterone levels. In addition, accumulation of menstrual blood behind an obstruction frequently results in cyclic abdominal pain or palpable abdominal mass. In women with outflow tract obstruction, an increase in retrograde menstruation may lead to development of endometriosis with associated complications such as chronic pain and infertility.

MÃ¼LLERIAN DEFECTS

During embryonic development, the mÃ¼llerian ducts give rise to the upper vagina, cervix, uterine corpus, and fallopian tubes (Fig. 18-1). MÃ¼llerian agenesis may be partial or complete. Accordingly, amenorrhea may result from outflow obstruction or from a lack of endometrium in cases involving uterine agenesis. In complete mÃ¼llerian agenesis, often called Mayer-Rokitansky-KÃ¼ster-Hauser syndrome, patients fail to develop any mÃ¼llerian structures and on examination are found to have only a vaginal dimple. In a report from Finland, approximately 1 in 5,000 newborn females were identified with this disorder, thus it ranks second only to gonadal dysgenesis as a cause of primary amenorrhea (Aittomaki, 2001; Reindollar, 1981).

The presentation of complete mÃ¼llerian agenesis may be confused with androgen insensitivity syndrome. In the latter condition, a patient has a 46,XY karyotype and functioning testes, however, the body cannot respond to testosterone due to mutations in the androgen receptor. These two syndromes are compared in Table 16-5 and discussed further in Chapter 18, Pathophysiology.

Acquired

Other abnormalities of the uterus that cause amenorrhea include obstruction due to stenosis of the cervix. This may result from conization, electrosurgery, or cryosurgery used to treat cervical dysplasia.

Amenorrhea may also be observed with extensive intrauterine scarring. The presence of this scar tissue, also called uterine synechiae, is termed Asherman syndrome (Fig. 16-2). In less severe cases, patients may present with hypomenorrhea or recurrent pregnancy loss.

The endometrium is divided into a functional layer, which lines the endometrial cavity, and a basal layer, which regenerates the functional layer with each menstrual cycle. Destruction of the basal endometrium prevents endometrial thickening in response to ovarian steroids. Therefore, no tissue is produced and subsequently passed when steroid hormone levels fall at the end of the luteal phase.

Endometrial damage may follow vigorous curettage, usually in association with postpartum hemorrhage, miscarriage, or therapeutic abortion complicated by infection. Damage may also result from other uterine surgery including metroplasty, myomectomy, or cesarean delivery, or from infection related to an intrauterine device. Although rare in the United States, tuberculous endometritis is a relatively common cause of Asherman syndrome in developing countries (Buttram, 1977; Klein, 1973). If they are surgically treated and achieve pregnancy, these patients must be monitored carefully because of the increased risk of uterine rupture or placenta accreta (Capella-Allouc, 1999; Deaton, 1989; Fernandez, 2006). Further discussion of Asherman syndrome is found in Chapter 18, Asherman Syndrome. Surgical lysis of these intrauterine adhesions is described in Section 41-41, Lysis of Intrauterine Adhesions.

ENDOCRINE DISORDERS

Hypergonadotropic Hypogonadism (Premature Ovarian Failure)

The term *hypergonadotropic hypogonadism* refers to any process in which ovarian function is decreased or absent (hypogonadism). Due to a lack of negative feedback, the gonadotropins, LH and FSH, have increased levels (hypergonadotropic). This category of disorders implies primary dysfunction at the level of the ovary, rather than centrally at the hypothalamus or pituitary. This process can also be termed *premature menopause* or *premature ovarian failure* (POF). The latter term is preferable, as it better describes the pathophysiology of this condition.

Premature ovarian failure is defined as loss of oocytes and the surrounding support cells prior to age 40 years. The diagnosis is determined by two serum FSH levels greater than 40 mIU/mL that are obtained at least 1 month apart. This definition distinguishes POF from the physiologic loss of ovarian function, which occurs with normal menopause. The incidence of premature ovarian failure has been estimated at 1 in 1,000 women less than 30 years, and 1 in 100 women less than 40 years (Coulam, 1986). A careful evaluation is mandatory (Premature Ovarian Failure). Nevertheless, in most cases, the etiology of POF is not determined.

HERITABLE DISORDERS

Chromosomal Defects

Gonadal dysgenesis is the most frequent cause of POF. In this disorder, although a normal complement of germ cells is present in the early fetal ovary, oocytes undergo accelerated atresia, and the ovary is replaced by a fibrous streak (Fig. 16-3) (Simpson, 1975; Singh, 1966). Individuals with gonadal dysgenesis may present with a variety of clinical features and can be divided into two broad groups based on whether the patient's karyotype is normal or abnormal (Schlessinger, 2002).

Abnormal Karyotype

Deletion of genetic material from an X chromosome accounts for about two thirds of gonadal dysgenesis (Devi, 1998; Tho, 1981). These patients are said to have Turner syndrome. A 45,X karyotype is found in about half of these patients, most of whom have associated somatic defects including short stature, webbed neck, low hairline, shield-shaped chest, and cardiovascular defects (Fig. 16-4 and Table 16-6) (Turner, 1972).

Drawing illustrating the classical phenotypic characteristics of women with Turner syndrome. Table 16-6 lists these physical traits.

The remaining patients with gonadal agenesis and identifiable abnormalities of the X chromosome have chromosomal mosaicism with or without associated structural abnormalities of the X chromosome. In these cases, the most common form of mosaicism is a 45,X/46,XX karyotype (Tho, 1981). Short stature and somatic abnormalities are most closely linked to deletions in the short arm of the X chromosome (Xp). Patients with deletion of the long arm of the X chromosome frequently have normal stature or may even have a eunuchoid body type. The low levels of estrogens in these patients results in delayed closure of the epiphyses of the long bones, resulting in long arms and legs relative to the torso. This appearance is termed a *eunuchoid habitus* (Baughman, 1968; Hsu, 1970).

Approximately 90 percent of individuals with gonadal dysgenesis due to loss of X genetic material never have menstrual bleeding. The remaining 10 percent have sufficient residual follicles to experience menses, and rarely may achieve pregnancy. However, the menstrual and reproductive lives of such individuals are invariably brief (Kaneko, 1990; Simpson, 1975; Tho, 1981).

In cases of gonadal agenesis, chromosomal mosaicism may also include the presence of a Y chromosome, such as 45,X/46,XY. Thus, chromosomal analysis should be performed in all cases of amenorrhea associated with POF, particularly before age 30. The presence of a Y chromosome cannot be determined clinically, as only a minority of patients will demonstrate signs of androgen excess. A streak gonad should be removed if Y chromosomal material is found, as nearly 25 percent of these patients will develop a malignant germ cell tumor (see Chap. 36) (Manuel, 1976; Simpson, 1975; Troche, 1986). In many cases, this can be accomplished laparoscopically (Wilson, 1992).

Normal Karyotype

The remaining one third of patients with gonadal dysgenesis will have a normal karyotype (46,XX or 46,XY) and are said to have "pure" gonadal dysgenesis. Patients with a 46,XY genotype are phenotypically female due to the lack of secretion of testosterone and mÃ¼llerian inhibiting substance by the dysgenetic testes. The etiology of the gonadal failure in both genetically male and female patients is poorly understood, but is likely due to single gene defects or destruction of gonadal tissue in utero, perhaps by infection or toxins.

Specific Genetic Defects

In addition to the chromosomal abnormalities described above, rarely patients may experience POF due to mutations in single genes. For example, mutation in the *CYP17* gene results in decreased 17-α-hydroxylase and 17,20-lyase activity, thereby preventing the production of cortisol, androgens, and estrogens (see Fig. 15-13). These patients have sexual infantilism and primary amenorrhea due to a lack of estrogen secretion. *Sexual infantilism* describes patients with a lack of breast development, lack of pubic and axillary hair, and a small uterus. Mutations in the *CYP17* gene also lead to an increase in adrenocorticotropin hormone (ACTH) secretion thereby stimulating mineralocorticoid secretion. This in turn leads to the development of hypokalemia and hypertension (Goldsmith, 1967).

Mutations in the LH and FSH receptors have also been reported in those with POF. These mutations prevent normal response to circulating gonadotropins, a condition termed *resistant ovary syndrome* (Aittomaki, 1995; Kim, 1974).

Galactosemia is a rare cause of POF. Inherited as an autosomal recessive disorder, this condition leads to abnormal galactose metabolism due to a deficiency of galactose-1-phosphate uridyl transferase, encoded by the *GALT* gene. Galactose metabolites are believed to have a direct toxic effect on germ cells. As a result, heterozygote carriers of this disorder may have suboptimal ovarian function. Galactosemia is frequently diagnosed during newborn screening programs or pediatric evaluation for associated growth and developmental impairment, and long before a patient would present to a gynecologist (Kaufman, 1981; Levy, 1984; Robinson, 1984).

ACQUIRED ABNORMALITIES

Hypergonadotropic hypogonadism can be acquired via infection, autoimmune disease, medical treatments, or from other causes. Infectious causes of POF are relatively rare and poorly understood, with mumps oophoritis most frequently reported (Morrison, 1975).

Autoimmune Disease

Autoimmune disorders are estimated to account for 40 percent of POF cases (Hoek, 1997; LaBarbera, 1988). Ovarian failure may be one component of polyglandular failure together with hypothyroidism, adrenal insufficiency, or other autoimmune disorders such as systemic lupus erythematosus. Although a number of anti-ovarian antibodies have been characterized, there is currently no validated serum antibody marker to assist in the diagnosis of autoimmune POF (American Society for Reproductive Medicine, 2006). Therefore, lacking a firm diagnosis, all women with POF should be evaluated for the presence of other autoimmune disorders (Premature Ovarian Failure). In addition to adrenal and thyroid disease, POF has been associated with myasthenia gravis, idiopathic thrombocytopenic purpura, rheumatoid arthritis, vitiligo, and autoimmune hemolytic anemia (Belvisi, 1993; de Moraes, 1972; Kalantaridou, 1998; Mignot, 1989).

Iatrogenic Causes

Iatrogenic ovarian failure is a relatively common presentation. This group includes patients who have undergone surgical complete removal or excision of a significant portion of the ovaries. A patient may experience amenorrhea following pelvic radiation for malignancies such as Hodgkin's disease. Preventively, ovaries should be surgically repositioned (oophoropexy) if possible, out of the anticipated radiation field prior to therapy (Horning, 1981).

Ovarian failure may also follow chemotherapy for treatment of malignancies or severe autoimmune diseases (Marhhom, 2007). Alkylating agents are believed to be particularly damaging to ovarian function. To minimize the resulting oocyte depletion, use of GnRH agonists or antagonists concurrent or prior to chemotherapy may be beneficial (Giuseppe, 2007; Pereyra, 2001; Somers,

2005).

A number of mechanisms by which GnRH analogs exert their protective effects have been proposed. These medications decrease ovarian blood flow, and thereby, decrease exposure of the ovaries to chemotherapeutic agents (Blumenfeld, 2003). Dividing cells are known to be more sensitive than cells at rest to the cytotoxic effects of these agents. Therefore, it has been suggested that inhibition of the pituitary-gonadal axis may protect the germinal epithelium by inhibiting oogenesis. Alternatively, as GnRH receptors have been identified in the ovary, GnRH agonists may act directly at the ovary to decrease granulosa cell metabolism (Peng, 1994). However, this explanation is not totally satisfactory, as the early stages of oogenesis occur independently of gonadotropin stimulation.

The chance of developing ovarian failure is correlated with increasing radiation and chemotherapeutic dose. Permanent ovarian failure almost invariably results from a dose of more than 8 Gy (800 rads) applied directly to the ovary (Ash, 1980). Patient age is also a significant factor, and younger patients are less likely to develop failure and more likely to regain ovarian function over time (Gradishar, 1989; Tham, 2007; Wallace, 1989).

A wide variety of environmental toxins have a clear detrimental effect on follicular health. These include cigarette smoking, heavy metals, solvents, pesticides, and industrial chemicals (Jick, 1977; Mlynarcikova, 2005; Sharara, 1998).

Hypogonadotropic Hypogonadism

The term *hypogonadotropic hypogonadism* implies that the primary abnormality lies in the hypothalamic-pituitary axis. A decrease in gonadotropin stimulation of the ovaries leads to loss of ovarian hormone production. Generally in these patients, LH and FSH levels, although low, will still be in the detectable range (<5 mIU/mL). However, levels may be undetectable in patients with complete absence of hypothalamic stimulation, such as occurs in Kallmann syndrome. In addition, absent pituitary function due to abnormal development or severe pituitary damage may lead to similarly low levels. The group of hypogonadotropic hypogonadism disorders may be viewed as a continuum with perturbations leading to luteal dysfunction, oligomenorrhea, and in the most severe presentation, amenorrhea.

DISORDERS OF THE HYPOTHALAMUS

Inherited Abnormalities

Inherited hypothalamic abnormalities primarily consist of those patients with idiopathic hypogonadotropic hypogonadism (IHH). Of these patients, a subset has associated defects in the ability to smell (hyposmia or anosmia) and are said to have Kallmann syndrome. This syndrome can be inherited as an X-linked, autosomal dominant or autosomal recessive disorder (Cadman, 2006; Layman, 1999; Waldstreicher, 1996). The X-linked form follows mutation in the *KAl1* gene on the X chromosome short arm, and is an uncommon cause of Kallman syndrome (Bhagavath, 2007). Expressed during fetal development, this gene encodes an adhesion protein, named anosmin-1, which is critical for normal migration of both GnRH and olfactory neurons from the olfactory placode to the hypothalamus and olfactory cortex, respectively (Franco, 1991; Soussi-Yanicostas, 1996). The autosomal dominant form of Kallmann syndrome accounts for about 10 percent of cases and is now known to be due to mutation in the gene which encodes fibroblastic growth factor receptor 1 (FGFR1) (Bhagavath, 2007).

Based on postmortem analyses, Kallmann patients have a normal complement of GnRH neurons, however, these neurons fail to migrate and remain near the nasal epithelium (Quinton, 1997). As a result, locally secreted GnRH fails to stimulate gonadotropin secretion by the anterior pituitary gland. Marked decreases in ovarian estrogen production result in a lack of breast development or menstrual cycles.

Kallmann syndrome is also associated with midline facial anomalies such as cleft palate, unilateral renal agenesis, cerebellar ataxia, epilepsy, neurosensory hearing loss, and synkinesis (mirror movements of the hands) (Winters, 1992; Zenaty, 2006). Kallmann syndrome can be distinguished from idiopathic hypogonadotropic hypogonadism (IHH) by olfactory testing. This can be done easily in the office with strong odorants such as ground coffee or perfume. Interestingly, many of these patients are unaware of their deficit.

ACQUIRED HYPOTHALAMIC DYSFUNCTION

Functional Disorders or Hypothalamic Amenorrhea

Inherited hypothalamic abnormalities are markedly less common than acquired deficiencies. Most frequently, gonadotropin deficiency leading to chronic anovulation is believed to arise from functional disorders of the hypothalamus or higher brain centers. Also called *hypothalamic amenorrhea* , this diagnosis encompasses three main categories: eating disorders, extreme exercise, and stress. From a teleologic perspective, amenorrhea in time of starvation or extreme stress can be seen as a mechanism to prevent pregnancy at a time in which resources are suboptimal for supporting a child. Each woman appears to have her own hypothalamic "set-point" or sensitivity to environmental factors. For example, individual women can tolerate significantly different amounts of stress without developing amenorrhea.

Eating Disorders

The eating disorders, anorexia nervosa and bulimia, can both result in amenorrhea. Anorexia nervosa is associated with severe caloric restriction, weight loss, self-induced vomiting, excess use of laxatives, and compulsive exercise (see Chap. 13, Eating Disorders). Weight loss is generally less severe in bulimic women, who eat in binges then purge to maintain weight.

Hypothalamic dysfunction is severe in anorexia and may affect other hypothalamic-pituitary axes in addition to the reproductive axis. Amenorrhea in anorexia nervosa can precede, follow, or appear coincidentally with weight loss. In addition, even with return to normal weight, not all women with anorexia will regain normal menstrual function.

Exercise-Induced Amenorrhea

This is most commonly seen in women whose exercise regimen is associated with significant loss of fat, such as ballet, gymnastics, and long-distance running (De Souza, 1991; Frisch, 1980). In those women who continue to menstruate, cycles are notable for their variability in cycle interval and menses length due to reduced hormonal function, including shortened luteal phases (De Souza, 1998). Puberty may be delayed in girls who begin training before menarche (Frisch, 1981).

In 1970, Frisch and Revelle proposed the concept that an adolescent girl required a critical body weight to begin menstruating. This mass was initially postulated to be approximately 48 kg and was subsequently refined to a minimal body mass index (BMI) approaching the normal level of ≥19 (BMI = wt [kilograms]/height [meters]) (Table 1-7) (Frisch, 1974a, 1974b). Subsequent studies have suggested that, although there is a clear correlation between body fat and reproductive function (at both ends of the weight spectrum), overall energy balance better predicts the onset and maintenance of menstrual cycles (Billewicz, 1976; Johnston, 1975). For example, many elite athletes regain menstrual cyclicity following a decrease in exercise intensity prior to any change in weight (Abraham, 1982).

Table 16-7 Tests Commonly Used in the Evaluation of Amenorrhea

Primary laboratory tests	**Diagnosis**
β-hCG	Pregnancy
FSH	Hypogonadotropic versus hypergonadotropic hypogonadism[a]
Estradiol	Hypogonadotropic versus hypergonadotropic hypogonadism
Prolactin	Hyperprolactinemia
TSH	Thyroid disease (hypothyroidism)
Secondary laboratory tests	
Testosterone	PCOS and exclude ovarian tumor
DHEAS	Exclude adrenal tumor
17-OH-P	Late-onset CAH

2-hour glucose tolerance test	PCOS
Fasting lipid panel	PCOS
Autoimmune testing	Premature ovarian failure
Karyotype	Premature ovarian failure <35 years
Radiologic evaluation	
Sonography	PCOS or to determine presence of uterus
HSG or saline-infusion sonography	MÃ¼llerian anomaly or intrauterine synechiae
Magnetic resonance imaging	MÃ¼llerian anomaly or hypothalamic-pituitary disease

[a] Hypogonadotropic hypogonadism includes functional causes of hypothalamic amenorrhea (excessive exercise, eating disorders, and stress). Hypergonadotropic hypogonadism refers primarily to premature ovarian failure.

CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; HSG = hysterosalpingography; 17-OH-P = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; TSH = thyroid-stimulating hormone.

Stress-Induced Amenorrhea

This may be associated with clearly traumatic life events, such as death of a family member or divorce. Nevertheless, much less severe life events and even positive events may be associated with stress. For example, stress-related amenorrhea is frequently associated with leaving for college, taking examinations, or wedding planning.

Eating disorders, exercise, and stress may alter menstrual function through overlapping mechanisms. This observation may be in part because these problems are often not found in isolation. For example, women with eating disorders frequently exercise excessively and are undoubtedly under stress as they attempt to control their eating patterns.

Pathophysiology of Functional Hypothalamic Amenorrhea

Figure 16-5 depicts a simplified model for the development of hypothalamic amenorrhea. It must be emphasized that each cause of functional hypothalamic amenorrhea may act via one or all of these pathways. Furthermore, in many cases, the factors known to impact reproductive function are likely acting indirectly on GnRH neurons via effects of various neuronal subtypes with synaptic connections to GnRH neurons.

FIGURE 16-5

Diagram depicting a simplified model for the development of amenorrhea in women with eating disorders, high stress levels, or rigorous exercise. Δ = change in; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; NPY = neuropeptide Y.

Exercise in particular has been associated with an increase in levels of endogenous opioids (β-endorphins), producing the so-called "runner's high". Opioids alter GnRH pulsatility as demonstrated by treatment of humans and animal models with anti-opiates, such as naloxone (see Chapter 15, Opioid Peptides and Gonadotropin-Releasing Hormone).

As part of the stress response, each of these conditions may lead to an increase in corticotropin-releasing hormone (CRH) release by the hypothalamus, which in turn results in cortisol secretion by the adrenal gland. Corticotropin-releasing hormone alters the pattern of pulsatile GnRH secretion, whereas cortisol may act directly or indirectly to disrupt GnRH neuronal function.

Eating disorders are thought to disrupt ovulatory function through a number of hormonal factors including insulin, glucagon, and leptin. First identified in 1994, leptin is a 167-amino acid protein encoded by the *ob* gene and produced in white adipose tissue (Zhang, 1994). Leptin receptors have been identified in the central nervous system as well as a wide range of peripheral tissues (Bjorbaek, 2004; Chen, 1996; Tartaglia, 1995, 1997).

Leptin provides an important link between energy balance and reproduction, albeit one of many mechanisms (Gonzalez, 2000; Schneider, 2004). Patients with anorexia nervosa have been found to have low circulating leptin levels (Mantzoros, 1997). Conversely, mutation of the human leptin gene results in morbid obesity, diabetes mellitus, and hypogonadism, which can be successfully reversed with recombinant human leptin (Janeckova, 2001; Licinio, 2004). Similarly, a mutation in the leptin-receptor gene has also been linked with hypogonadism and obesity (Farooqi, 2007).

This has led to the concept of leptin as a "satiety factor". It has been hypothesized that a decrease in leptin production due to

weight loss could secondarily stimulate neuropeptide Y, which is known to stimulate hunger and alter GnRH pulsatility. Leptin likely acts through a wide variety of additional neurotransmitters and neuropeptides including β-endorphins and α-melanocyte stimulating hormone (Tartaglia, 1995).

Pseudocysesis

Although rare, this diagnosis should be considered in any woman presenting with amenorrhea and pregnancy symptoms. Pseudocyesis exemplifies the ability of the mind to control physiologic processes. Approximately 550 cases have been reported in the medical literature in women ranging from 6 to 79 years. These patients fervently believe that they are pregnant and subsequently demonstrate a number of the signs and symptoms of pregnancy, including amenorrhea.

Endocrine evaluation in a limited number of patients has failed to demonstrate a consistent pattern of hormonal derangements. Alterations in LH pulse frequency in conjunction with elevated serum androgen levels may explain the development of amenorrhea. Elevated serum prolactin levels with resultant galactorrhea have been noted in a subset of patients. Growth hormone secretion appears to be blunted.

A common link in these patients is a history of severe grief, such as recent miscarriage or infant death. Psychiatric treatment is generally required to treat the associated depression, which is often exacerbated when the patient is informed that she is not pregnant (Bray, 1991; Starkman, 1985; Whelan, 1990).

Anatomic Destruction

Any process that destroys the hypothalamus can impair GnRH secretion and lead to the development of hypogonadotropic hypogonadism and amenorrhea. Due to the complex interaction of input to the GnRH neurons, these abnormalities do not need to directly impact the GnRH neurons, but may operate indirectly by altering activity of modulatory neurons.

Tumors most often associated with amenorrhea include craniopharyngiomas, germinomas, endodermal sinus tumors, eosinophilic granuloma (Hand-SchÃ¼ller-Christian syndrome), and gliomas, as well as metastatic lesions. The most common of these tumors, craniopharyngiomas, are located in the suprasellar region, and patients frequently present with headaches and visual changes.

Impaired GnRH secretion has also been reported with infections, such as tuberculosis, and with infiltrative diseases, such as sarcoidosis. Trauma or radiation to the hypothalamus can also result in hypothalamic dysfunction and subsequent amenorrhea.

ANTERIOR PITUITARY GLAND

The anterior pituitary gland consists of gonadotropes (producing LH and FSH), lactotropes (prolactin), thyrotropes (thyroid-stimulating hormone), corticotropes (adrenocorticotropin hormone), and somatotropes (growth hormone) (see Chap. 15, Anterior Pituitary Gland). Although various disorders may directly affect gonadotropes, many causes of pituitary-derived amenorrhea may also follow abnormalities in other pituitary cell types, which in turn, alter gonadotrope function.

Inherited Abnormalities of the Pituitary Gland

Rapid advances are being made in our understanding of the genetic mechanisms that regulate normal hypothalamic and pituitary development and function. Mutations resulting in the hypothalamic defect, Kallmann syndrome (hypogonadotropic hypogonadism with anosmia), have been described earlier. Additional genes known to affect hypothalamic development or function in the human will be mentioned here for completeness. Note that the clinical features observed in affected patients may vary widely depending on the severity of dysfunction that follows genetic mutation. Conversely, an identical mutation may have variable expression and clinical effects.

An increasing number of cohorts have been described with combined pituitary hormone deficiency and central facial and/or neurologic defects due to a failure of midline fusion. Known as septoptic dysplasia, many of these patients have a mutation in the *PROP1* gene (Cadman, 2006; Layman, 1999; Vesper, 2006). Mutations in genes that encode the LH or FSH β-subunits or the GnRH-receptor have also been identified as rare causes of hypogonadotropic hypogonadism. Hypothalamic and pituitary dysfunction with associated gonadal agenesis and adrenal hypoplasia has been well described in patients with mutations in the nuclear hormone receptors, steroidogenic factor-1 (SF-1; NR5A1) and DAX1 (NR0B1) (Beranova, 2001; Layman, 1997, 1998; Matthews, 1993; Weiss, 1992). Most recently, attention has focused on kisspeptin-1 and its receptor, G-protein-coupled receptor

54 (GPR54). Mutations in this receptor result in delayed puberty and hypogonadotropic hypogonadism, demonstrating that this ligand-receptor system is a critical stimulus of GnRH secretion (Pallais, 2006; Seminara, 2006).

Acquired Pituitary Dysfunction

Most pituitary dysfunction is acquired after menarche, and therefore, women present with normal pubertal development followed by secondary amenorrhea. Nevertheless, in rare cases, these disorders may develop prior to puberty, resulting in delayed pubertal development and primary amenorrhea (Howlett, 1989).

Pituitary adenomas are the most common cause of acquired pituitary dysfunction (see Chap. 15, Pituitary Adenomas). The most common adenomas secrete prolactin, however, altered secretion of any pituitary-derived hormone can result in amenorrhea.

As many as one tenth of amenorrheic women have increased levels of serum prolactin and more than half of women with both galactorrhea and amenorrhea have elevated prolactin levels (the "galactorrhea-amenorrhea syndrome"). Dopamine is the primary regulator of prolactin biosynthesis and secretion. Elevated prolactin levels are associated with a reflex increase in central dopamine production, which alters GnRH neuronal function.

Pituitary tumors also may indirectly alter gonadotrope function via a mass effect. This mass may compress neighboring gonadotropes or may damage the pituitary stalk, disrupting dopamine inhibition of prolactin secretion. Secondarily elevated prolactin levels presumably interfere with menstrual function through the same mechanisms described for primary prolactinomas above.

As in the hypothalamus, pituitary function may be disrupted by inflammation, infiltrative disease, or metastatic lesions. Although a rare condition, peripartum lymphocytic hypophysitis can be a dangerous cause of pituitary failure. Infiltrative diseases include sarcoidosis and hemochromatosis. In addition, loss of anterior pituitary function may be observed following surgical or radiation treatment of pituitary adenomas.

Sheehan syndrome refers to panhypopituitarism that develops after massive postpartum hemorrhage complicated by hypotension (Kelestimur, 2003). In its most severe form, patients develop shock and pituitary apoplexy. Loss of gonadotrope activity results in anovulation and subsequent amenorrhea. Damage to the other pituitary cell types may present as failure to lactate, loss of sexual and axillary hair, hypothyroidism, and adrenal insufficiency. The pituitary cell types are differentially sensitive to damage. Prolactin secretion deficiency is the most common, followed by loss of gonadotropin and growth hormone release, loss of ACTH, and least commonly, by decreases in thyroid-stimulating hormone (TSH) secretion (Veldhuis, 1980).

OTHER CAUSES OF HYPOGONADOTROPIC HYPOGONADISM

Hypogonadotropic amenorrhea may be observed in a wide variety of chronic diseases including end-stage kidney disease, liver disease, malignancies, acquired immunodeficiency syndrome, and malabsorption syndromes.

Eugonadotropic Amenorrhea

A number of disorders that produce amenorrhea are not associated with significantly abnormal gonadotropin levels. In these patients, chronic steroid secretion interferes with the normal feedback between the ovary and the hypothalamic-pituitary axis. The lack of cyclicity interferes with normal oocyte maturation, and menstruation fails to occur.

Due to relatively normal gonadotropin levels, these patients will secrete estrogen and therefore can be said to have *chronic anovulation with estrogen present.* This is in contrast to the patients with ovarian failure or hypothalamic-pituitary failure in which estrogen is low. This distinction may be useful during evaluation and treatment.

POLYCYSTIC OVARIAN SYNDROME

This syndrome is by far the most common cause of chronic anovulation with estrogen present (see Chap. 17). Patients with polycystic ovarian syndrome (PCOS) may have a wide variety of menstrual presentations, ranging from occasional ovulatory cycles to menometrorrhagia secondary to unopposed estrogen stimulation of the endometrium to complete amenorrhea. Amenorrhea in PCOS patients may be attributable in part to the atrophic effects of androgens on endometrial proliferation.

Polycystic ovarian syndrome can be appropriately characterized as an inherited form of eugonadotropic amenorrhea. Although a

specific gene defect has not been identified, there is an increased incidence of PCOS in the mothers and sisters of affected individuals. An elevated ratio of LH:FSH levels (greater than twofold) has been noted in most patients, however, the LH level remains in the normal or high-normal range.

ADULT-ONSET CONGENITAL ADRENAL HYPERPLASIA

This condition closely mimics the presentation of PCOS, with hyperandrogenism and irregular menstrual cycles. Most commonly, late-onset congenital adrenal hyperplasia (CAH), also termed adult-onset CAH, is due to a mutation in the *CYP21* gene, which encodes the 21-hydroxylase enzyme. With a mild mutation, patients are asymptomatic until adrenarche and its associated requirement for increased adrenal steroidogenesis. Patients with CAH are unable to convert an adequate percentage of progesterone to cortisol and aldosterone, thus increasing the production of androgens (see Fig. 15-13). As in PCOS, elevated androgen levels blunt oocyte maturation and thereby result in anovulation and amenorrhea. Congenital adrenal hyperplasia is additionally discussed in Chapter 15, Congenital Adrenal Hyperplasia and 18, Pathophysiology.

OVARIAN TUMOR

Although uncommon, chronic anovulation with estrogen present can also be observed with ovarian tumors producing either estrogens or androgens. Examples of these neoplasms include granulosa cell tumors, and thecal cell tumors, which are sex steroid-stromal tumors (see Chap. 36, Ovarian Sex Cordâ€“Stromal Tumors).

HYPERPROLACTINEMIA AND HYPOTHYROIDISM

As discussed above, hyperprolactinemia can be categorized as a cause of pituitary hypogonadotropic hypogonadism. Of note, however, many of these patients may have relatively normal gonadotropin levels, although as a group their estrogen levels will be mildly depressed. Thyroid disease is also a relatively common cause of oligomenorrhea associated with gonadotropins in the normal range. Classically, hypothyroidism is stated to cause amenorrhea, whereas hyperthyroidism is implicated in menorrhagia.

A mechanism by which hyperprolactinemia and hypothyroidism may lead to amenorrhea is outlined in Figure 16-6. In this model, a primary decrease in circulating thyroid hormone levels, for example due to Hashimoto thyroiditis, leads to a compensatory increase in hypothalamic thyrotropin-releasing hormone (TRH). As part of the thyroid axis, TRH increases TSH by the pituitary gland thyrotropes. In addition, TRH also binds to the pituitary lactotropes, increasing prolactin secretion.

Diagram depicting a simplified model for the development of amenorrhea in women with hyperprolactinemia or hypothyroidism. Δ = change in; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

An increase in circulating prolactin results in a compensatory increase in central dopamine, the primary inhibitor of prolactin secretion. The increase in central dopamine levels alters GnRH secretion, thereby disrupting normal cyclic gonadotropin secretion and preventing ovulation. Note that this increase in prolactin may be primary, for example from a prolactinoma, or may be secondary due to an elevation in TRH. In secondary hyperprolactinemia, prolactin levels are generally lower and less than 100 ng/mL.

There are undoubtedly other mechanisms by which thyroid disease and elevated prolactin levels disturb menstrual function, but these are poorly understood at present. For example, thyroid receptors are found in most cell types. Moreover, thyroid hormone increases sex-hormone binding globulin levels, altering the levels of unbound, and thereby active, ovarian steroids. In addition, prolactin receptors have been identified in the ovary and in the endometrium.

EVALUATION

History

An algorithm for approaching the patient with amenorrhea is presented in Figure 16-7. The evaluation of menstrual abnormalities should start with questions regarding pubertal development. Did the patient experience normal puberty in terms of onset and progression (see Chap. 14, Pubertal Changes)? Did she ever achieve regular menstrual cyclicity? The cycle interval, duration, and amount of menstrual flow should be characterized. It is important to determine when a change in this pattern was noted and whether the change was sudden or gradual. Did the development of amenorrhea correlate with pelvic infection, surgery, radiation, chemotherapy, or other illness?

FIGURE 16-7

Diagnostic algorithm to evaluate amenorrhea. AIS = androgen insensitivity syndrome; CAH = congenital adrenal hyperplasia; DHEA-S = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; IHH = idiopathic hypogonadotropic hypogonadism; MRI = magnetic resonance imaging; 17-OH-P = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; POF = premature ovarian failure; TSH = thyroid-stimulating hormone.

In addition, a thorough medical history should be obtained. A surgical history should focus on prior pelvic surgery, particularly intrauterine surgery, including dilatation and curettage. Complications associated with uterine surgery, particularly infection, should be sought.

A focused review of symptoms can also be helpful in defining the etiology of amenorrhea. For example, new-onset headaches or visual changes may suggest a tumor of the central nervous system or pituitary gland. Spontaneous bilateral breast discharge is consistent with a diagnosis of hyperprolactinemia. The presence of thyroid disease may be associated with heat or cold intolerance, weight changes, and sleep abnormalities. Hot flashes and vaginal dryness suggest hypergonadotropic hypogonadism or POF. Hirsutism and acne are frequently seen with PCOS, or with late-onset CAH. Cyclic pelvic pain would suggest a reproductive tract outlet obstruction.

Important questions regarding family history include premature cessation of menses or a history of autoimmune disease, including thyroid disease, which would suggest an increased risk for POF. A family history of irregular menses, infertility, or signs of excess androgen production may be noted in a patient with PCOS. Sudden neonatal death may have occurred in family members carrying mutations in the *CYP21* gene responsible for classic CAH.

The social history should investigate exposure to environmental toxins, including cigarettes. Any medications, especially those that increase prolactin levels such as antipsychotics should be noted (see Table 12-4).

Physical Examination

A thorough physical examination will frequently provide a diagnosis, although testing is still indicated. General appearance can be helpful in the evaluation of amenorrhea. A low body mass index, perhaps in conjunction with loss of tooth enamel due to recurrent vomiting, is highly suggestive for an eating disorder. Signs of Turner syndrome should be evaluated, including the presence of short stature and other stigmata such as webbed neck or shield-shaped chest. Midline facial defects, such as cleft palate, are consistent with a developmental defect of the anterior pituitary gland. Hypertension in a prepubertal girl would be consistent with mutation in the *CYP17* gene and CAH.

Visual field changes, particularly bitemporal hemianopsia, or other visual defects may be indicative of a tumor in the pituitary gland or central nervous system.

Skin should be inspected for acanthosis nigricans, hirsutism, or acne, which may indicate PCOS or other causes of hyperandrogenism (see Figs. 17-7). The presence of supraclavicular fat and abdominal striae with hypertension may be noted in those with Cushing syndrome. Hypothyroidism may present with an abnormally enlarged thyroid gland, delayed reflexes, and bradycardia. On breast examination, bilateral galactorrhea implies the presence of hyperprolactinemia. A more complete discussion of the evaluation and treatment of galactorrhea can be found in Chapter 12, Nipple Discharge.

Examination of the genitalia should start by noting hair pattern. Sparse or absent female pubic hair may be due to either lack of adrenarche or androgen insensitivity syndrome. Conversely, elevated androgen levels will result in a male pattern of genital hair growth. In contrast to the triangular pattern of hair in females, male abdominal wall hair extends to the umbilicus, forming a triangle, or male escutcheon (see Fig. 17-3). Markedly elevated levels of androgens will produce signs of virilization, most noticeably clitoromegaly. These women may also note voice deepening and male pattern balding.

Evidence of estrogen production includes a pink moist vagina and cervical mucus. A vaginal smear will demonstrate a majority of superficial epithelial cells (see Fig. 21-12).

Determination of mÃ¼llerian anomalies by physical examination is described in Chapter 18, MÃ¼llerian Anomalies. A rectal examination may help identify a uterus above an obstruction at the level of the introitus or in the vagina. The presence of hematocolpos suggests normal ovarian and endometrial function.

Laboratory and Radiologic Testing

Although the differential diagnosis of amenorrhea is extensive, evaluation of most women is relatively straightforward. As for all disorders, testing will be modified by patient history and physical examination.

EXCLUSION OF PREGNANCY

All reproductive-aged women with amenorrhea should be assumed pregnant until proven otherwise. Therefore, it is always prudent to measure a urinary or serum β-hCG level.

PROGESTERONE WITHDRAWAL

Classically, patients are given exogenous progesterone and monitored for a progesterone withdrawal bleed, which follows a few days after completion of progesterone (progesterone challenge test). If bleeding ensues, then a woman is assumed to produce estrogen and to have an intact endometrium and patent outflow tract. If bleeding does not follow, then a patient is given estrogen followed by progesterone treatment. If a woman again fails to bleed, then an anatomic abnormality is diagnosed.

However, a number of factors can lead to an incorrect test interpretation. First, estrogen levels may fluctuate in both hypothalamic amenorrhea and in the early stages of ovarian failure. As a result, patients with these disorders may have at least some bleeding after progesterone withdrawal. Furthermore, women with high androgen levels, such as occurs with PCOS and CAH, may have an atrophic endometrium and fail to bleed. Specifically, up to 20 percent of women in whom estrogen is present will fail to bleed following progesterone withdrawal (Rarick, 1990). Conversely, menses may be observed in up to 40 percent of women with hypothalamic amenorrhea due to stress, weight loss, or exercise, and in up to 50 percent of women with ovarian failure after progesterone administration (Nakamura, 1996; Rebar, 1990).

SERUM HORMONE LEVELS

As suggested by the American Society for Reproductive Medicine (2006), it may be more reasonable to begin with hormonal evaluation in any woman found to have a normal pelvic examination (Table 16-7).

Follicle-Stimulating Hormone

A normal FSH level suggests an anatomic defect or eugonadotropic hypogonadism, such as PCOS. In contrast, an elevated FSH level is consistent with ovarian failure, and a low level suggests hypothalamic-pituitary dysfunction.

Patients with PCOS, hyperprolactinemia, or thyroid disease would be expected to have normal FSH levels. Although many patients with PCOS have elevated LH:FSH level ratios (>2), testing for this relationship is unnecessary, as a normal ratio does not exclude this diagnosis.

An elevated FSH level strongly suggests the presence of hypergonadotropic hypogonadism (premature ovarian failure). This diagnosis requires two FSH levels >40 mIU/mL obtained at least 1 month apart. Many clinicians will simultaneously obtain an estradiol level to further confirm the diagnosis, although this has not been shown to substantially increase diagnostic accuracy. At least two elevated values are required because the course of POF may fluctuate over time. It is likely that this fluctuation explains the occasional pregnancy that has been reported in these patients. Patients should keep a menstrual calendar while testing is completed, as bleeding 2 weeks following an elevated serum FSH level may simply indicate that the sample was obtained during a gonadotropin surge.

If an FSH value is low, it may be helpful to repeat this measurement with the addition of an LH level to confirm hypogonadotropic hypogonadism. Additional testing may include a GnRH stimulation test. Although a number of different protocols have been employed, one common approach has been intravenous injection of 100 μg of GnRH as a bolus followed by measurement of LH and FSH at 0, 15, 30, 45, and 60 minutes. Although both LH and FSH levels will be blunted, FSH levels will be high relative to LH ratios in patients with hypogonadotropic hypogonadism or delayed puberty (Job, 1977; Yen, 1973). Although informative, in practice this test is often unable to be performed due to a lack of consistently available clinical-grade GnRH.

Prolactin and Thyroid-Stimulating Hormone

These hormone levels should be tested in most patients with amenorrhea, as prolactin-secreting adenomas and thyroid disease are

relatively common and require specific treatment. Furthermore, hypothyroidism may secondarily lead to elevated prolactin levels as shown in Figure 16-6. Because of this close relationship between thyroid disease and prolactin levels, both hormones should be measured simultaneously. Treatment for hypothyroidism will also normalize prolactin levels. Regrettably, it is not uncommon for patients to be imaged and subsequently treated for hyperprolactinemia with delay in diagnosis of their primary hypothyroidism (Poretsky, 1986).

Testosterone

Serum levels of this hormone should be measured in any woman with suspected PCOS or with clinical signs of androgen excess. Hormonal evaluation should include evaluation of serum total testosterone levels. Measurement of free testosterone levels is generally unwarranted, as these assays are more expensive and more variable. Mild elevations in testosterone levels are consistent with the diagnosis of PCOS. However, values exceeding 200 ng/dL are consistent with the presence of an ovarian tumor and should be evaluated with pelvic sonography.

Dehydroepiandrosterone Sulfate

Secretion of this hormone is essentially limited to the adrenal gland. High normal levels or even very mild elevations are consistent with PCOS. In contrast, adrenal adenomas may produce circulating DHEAS levels above 700 μg/dL and warrant investigation with magnetic resonance (MR) imaging or computed tomography (CT) of the adrenals. Measurement of 17-hydroxyprogesterone (17-OH-P) aims to identify patients with late-onset CAH. However, confirmation of this diagnosis can be difficult due to the overlap in values among normal patients and heterozygote and homozygote carriers of mutations in the gene that encodes 21-hydroxylase (*CYP21A2*). Therefore, stimulation with ACTH, often colloquially termed the *cort stim test,* may be required (see Chap. 17, 17-Hydroxyprogesterone).

OTHER SERUM TESTING

If there is any suggestion of an eating disorder, an immediate assessment of serum electrolytes is indicated, as imbalances can be life-threatening. An electrocardiogram should also be considered in those patients perceived to have more severe disease. A reverse triiodothyronine (T_3) level is often elevated in patients with functional hypothalamic amenorrhea.

Women with PCOS should be screened for insulin resistance and lipid abnormalities, as these are commonly found in affected patients and increase risks for development of diabetes and cardiovascular disease (see Chap. 17, Impaired Glucose Tolerance and Type 2 Diabetes Mellitus). Although no consensus exists, it is probably prudent to repeat these tests every few years in these women.

RADIOLOGIC EVALUATION

Any patient with hypogonadotropic hypogonadism should be assumed to have an anatomic abnormality until proven otherwise by imaging of the brain and pituitary gland with MR imaging or a CT scan. Thus, functional hypothalamic amenorrhea due to stress, exercise, or eating disorder is a diagnosis of exclusion. Imaging is highly sensitive for identification of destructive disorders such as tumors or infiltrative diseases of the hypothalamus or pituitary. Patients with Kallmann syndrome frequently demonstrate defects in the development of the olfactory bulbs and sulci of the rhinencephalon (Klingmuller, 1987).

CHROMOSOMAL ANALYSIS

Patients with gonadal dysgenesis, such as Turner syndrome, should be considered for karyotype testing. Classic teaching suggests that this test is unnecessary after age 30. However, consideration should be given to testing patients up to age 35 years, as a rare patient with mosaicism may sustain cyclic menses longer than expected. As previously indicated, a Y-cell line requires bilateral oophorectomy because of the increased risk for ovarian tumors. Due to the close association between stature and abnormalities in the X-chromosome, many specialists advise karyotyping all women with POF who are shorter than 60 inches. Chromosomal studies should also be considered in any woman with a familial history of POF.

SPECIFIC DISORDERS

Premature Ovarian Failure

Many patients with POF will not have a clear etiology for their disorder. Presumption of an autoimmune cause is probably wise,

based on the potential long-term consequences of these disorders. Testing varies widely among experts, but those that may be associated with POF are listed in Table 16-8.

Table 16-8 Evaluation of Premature Ovarian Failure Due to Presumptive Autoimmune Disease

Test(s)	Target Organ
Free T4, TSH, ATA, AMA	Thyroid
Calcium, phosphorus, albumin	Parathyroid
ACTH	Adrenal
Fasting glucose	Islet cells
Complete blood count	Red blood cells (hemolytic anemia or pernicious anemia)
Platelets	Idiopathic thrombocytopenia
ANA, RF, ESR	General autoimmune disease screen

ACTH = adrenocorticotropin hormone; AMA = anti-microsomal antibody; ANA = anti-nuclear antibody; ATA =anti-thyroid antibody; ESR = erythrocyte sedimentation rate; RF = rheumatoid factor; TSH = thyroid-stimulating hormone; T4 = thyroxine.

Anatomic Disorders

These can be evaluated with a number of modalities depending on the suspected etiology. Sonographic examination is frequently useful as a first screen for those with a grossly normal uterus. Hysterosalpingography (HSG) and saline-infusion sonography (SIS) are excellent for the detection of intrauterine synechiae or developmental anomalies (see Chaps. 2, Infertility and 19, Uterine Pathology). Magnetic resonance (MR) imaging is frequently used for delineation of anatomic structures, such as mÃ¼llerian anomalies and others (see Figs. Chaps. 2, Congenital Anomalies and 18, Diagnosis and Treatment).

MÃ¼llerian dysgenesis may be associated with a variety of malformations in other organ systems. With complete mÃ¼llerian agenesis, approximately one third of patients will have urinary tract abnormalities including an ectopic kidney, unilateral renal agenesis, horseshoe kidney, or abnormal collecting ducts. Skeletal anomalies, generally of the spine, may be present in up to 12 percent of these patients (Fore, 1975; Griffin, 1976). A renal sonographic examination and lower spine radiographic evaluation will detect these associated anomalies. The incidence of these related anomalies differs between the types of mÃ¼llerian dysgenesis. They are probably most common with complete agenesis or duplication anomalies, such as bicornuate uterus or uterine didelphys, and less common with disorders of resorption, such as a uterine septum (Fedele, 1990; Letterie, 1988; Reinhold, 1997). For this reason, most experts feel that additional anatomic evaluation is not required in those with a uterine septum and no other uterine anomalies.

Magnetic resonance (MR) imaging is also helpful to detect endometrial tissue in a uterus or uterine horns. A noncommunicating uterine horn with a clear endometrial stripe should be removed in most instances, as it increases the risk of endometriosis and may ultimately cause pain due to distension with menstrual blood. Furthermore, if a pregnancy occurs in this horn, it will almost invariably lead to uterine rupture.

TREATMENT

The treatment of amenorrhea depends on the etiology as well as the aims of the patient, such as a desire to treat hirsutism or to become pregnant.

Anatomic abnormalities will require surgical correction, if possible. Hypothyroidism should be treated with thyroid replacement, and patients with hyperprolactinemia should receive a dopamine agonist, such as bromocriptine or cabergoline (see Chap. 15, Treatment of Pituitary Adenomas). Macroadenomas may require surgery if secondary deficits, such as visual changes, are observed

(see Chap. 15, Pregnancy and Pituitary Adenomas).

Estrogen Replacement

This therapy should be instituted in essentially every patient with hypogonadism to avoid osteoporosis (see Chap. 21, Bone Metabolism and Structural Changes). As in postmenopausal women, bone loss is accelerated in the first few years following estrogen deprivation, and therefore treatment should be instituted quickly. Women with a uterus also require continuous or intermittent progesterone administration to protect against endometrial hyperplasia or cancer (see Chap. 22, Summary of Current Use Indications).

There is no consensus, however, on an optimal regimen in these patients. A listing of available estrogens and progestins used for hormone replacement therapy is found in Table 22-2. Some experts recommend that women in their twenties should receive higher doses of estrogen than is routinely given to postmenopausal women, as this is a time of ongoing bone deposition. Frequently, it is easiest to prescribe combination oral contraceptive pills. Younger women may prefer this treatment, as their friends may also use these pills, and in their minds hormone replacement therapy may be associated with aging. Additionally, there is also no consensus on the duration of treatment in this patient population. For most patients, continuation until approximately age 50, the usual age of menopause, seems reasonable.

Patients who have eating disorders or who exercise excessively will require behavior modification. In a patient with an eating disorder, psychiatric intervention is imperative due to the significant morbidity and mortality associated with this diagnosis (American Psychiatric Association, 2000). Elite athletes may choose not to alter their exercise regimens and will therefore require estrogen treatment.

Polycystic Ovarian Syndrome

Treatment of affected women may include cyclic progesterone treatment or oral contraceptives or other forms of estrogen-progesterone treatment (see Chap. 17, Combination Oral Contraceptive Pills). Insulin-sensitizing agents such as metformin (Glucophage, Bristol-Myers Squibb, New York, NY) may be indicated in those with insulin resistance. Hyperandrogenism due to PCOS may be treated with oral contraceptives and/or spironolactone.

Women with late-onset CAH may be treated with low-dose corticosteroids to partially block ACTH stimulation of adrenal function and thereby decrease overproduction of adrenal androgens.

Infertility

Treatments may require modification if a woman desires conception. Adequate treatment of hyperprolactinemia and thyroid disease will result in ovulation and in normal fertility for most women. Anatomic abnormalities will often require attempts at surgical correction. However, if adequate correction is impossible, pregnancy will require use of a surrogate to carry a gestation. Premature ovarian failure cannot be corrected, and these patients will require in vitro fertilization using a donor oocyte to conceive. In contrast, patients with hypogonadotropic hypogonadism typically require treatment with pulsatile GnRH or gonadotropins. As pulsatile GnRH is more complex to administer, most patients receive gonadotropin therapy from an infertility specialist. Patients with PCOS will frequently ovulate following clomiphene citrate treatment. Clomiphene citrate is believed to act by transient inhibition of estrogen feedback at the hypothalamus and pituitary gland. Therefore, this treatment will not be effective in patients with hypogonadotropic hypogonadism, as they lack estrogen synthesis.

Patient Education

Finally, as in all medical conditions, it is critical that patients be adequately counseled about their diagnosis, the long-term implications of this diagnosis, and the treatment options. Even if not raised by the patient, the potential for future childbearing should be discussed. Many women are under the mistaken impression that it is dangerous not to have a menstrual period, and should be reassured that this is, in and of itself, not a concern. On the other hand, all women with an intact endometrium should understand the risks of unopposed estrogen action, whether the estrogen is exogenous such as through hormone therapy, or endogenous such as in PCOS. Hypoestrogenic women should be counseled about the importance of estrogen replacement to protect against bone loss. As discussed in Chapter 22, Summary of Current Use Indications, estrogen may have additional benefits, which

should also be discussed with these women.

POLYCYSTIC OVARIAN SYNDROME AND HYPERANDROGENISM: INTRODUCTION

Polycystic ovarian syndrome (PCOS) is a common endocrinopathy typified by oligo-ovulation or anovulation, signs of androgen excess, and multiple small ovarian cysts. These signs and symptoms may vary widely between women as well as within individuals over time. As a result, women with PCOS may present to various medical specialists, including gynecologists, internal medicine specialists, endocrinologists, or dermatologists. Thus, a familiarity with PCOS is essential for physicians in each of these specialties.

INCIDENCE

Polycystic ovarian syndrome is the most common endocrine disorder of reproductive-aged women and affects approximately 4 to 12 percent (AsunciÃ³n, 2000; Diamanti-Kandarakis, 1999; Farah, 1999: Knochenhauer, 1998). Although symptoms of androgen excess may vary between ethnicity, PCOS appears to equally affect all races and nationalities.

DEFINITIONS

Polycystic Ovarian Syndrome

In 2003 in Rotterdam, Netherlands, a consensus meeting between the European Society of Human Reproduction and Embryology and the American Society for Reproductive Medicine (ESHRE/ASRM) (The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004) redefined PCOS (Table 17-1). Affected individuals must have two out of the following three criteria: (1) oligo- and/or anovulation, (2) hyperandrogenism (clinical and/or biochemical), and (3) polycystic ovaries on sonographic examination. However, because other etiologies, such as congenital adrenal hyperplasia, androgen-secreting tumors, and hyperprolactinemia, may also lead to oligo-ovulation and/or androgen excess, these must be excluded. Thus, PCOS is at present a diagnosis of exclusion.

Table 17-1 Definition of Polycystic Ovarian Syndrome
ESHRE/ASRM (Rotterdam) 2003 To include two out of three of the following: 1. Oligo or anovulation 2. Clinical and/or biochemical signs of hyperandrogenism 3. Polycystic ovaries (with the exclusion of related disorders)
NIH (1990) To include both of the following: 1. Oligo-ovulation 2. Hyperandrogenism and/or hyperandrogenemia (with the exclusion of related disorders)

ASRM = American Society of Reproductive Medicine; ESHRE = European Society of Human Reproduction and Embryology; NIH = National Institutes of Health.

From The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004, and Zawadzki, 1990, with permission.

The Rotterdam criteria constitute a broader spectrum than that formerly put forward by the National Institutes of Health (NIH) Conference in 1990 (Zawadzki, 1990). The latter defined PCOS by ovulatory dysfunction plus clinical hyperandrogenism and/or hyperandrogenemia without regard to ovarian sonographic appearance. Controversy exists as to which definition is more appropriate, and many investigators still use the NIH 1990 criteria as a basis to define PCOS in their population studies (Chang, 2005).

Ovarian Hyperthecosis and HAIRAN Syndrome

Often considered a more severe form of PCOS, *ovarian hyperthecosis* is a rare condition characterized by nests of luteinized theca cells distributed throughout the ovarian stroma. Affected women exhibit severe hyperandrogenism, and may occasionally display frank virilization signs such as clitoromegaly, temporal balding, and deepening of the voice (Culiner, 1949). In addition, there is typically a much greater degree of insulin resistance and acanthosis nigricans (Nagamani, 1986).

The hyperandrogenic-insulin resistant-acanthosis nigricans (HAIRAN) syndrome is uncommon and consists of marked hyperandrogenism, severe insulin resistance, and acanthosis nigricans (Barbieri, 1994). The etiology of this disorder is unclear, and HAIRAN syndrome may represent either a variant of PCOS or a distinct genetic syndrome.

ETIOLOGY

The underlying cause of PCOS is unknown. However, a genetic basis that is both multifactorial and polygenic is suspected, as there is a well-documented aggregation of the syndrome within families (Franks, 1997). Specifically, an increased prevalence has been noted between affected individuals and their sisters (32 to 66 percent) and mothers (24 to 52 percent) (Govind, 1999; Kahsar-Miller, 2001; Yildiz, 2003). Some have suggested an autosomal dominant inheritance with expression in both females and males. For example, first-degree male relatives of women with PCOS have been shown to have significantly higher circulating dehydroepiandrosterone sulfate (DHEAS) levels than control males (Legro, 2002).

Identification of candidate genes linked to PCOS has been a major research focus, given the large potential benefit for both diagnosis and management of this disorder. Clinical and in vitro studies of human ovarian theca cells have suggested dysregulation of the *CYP11a* gene in patients with PCOS. This gene encodes the cholesterol side-chain cleavage enzyme, the enzyme that performs the rate-limiting step in steroid biosynthesis(see Fig. 15-13). Evidence also suggests upregulation of other enzymes in the androgen biosynthetic pathway (Franks, 2006). In addition, the insulin receptor gene on chromosome 19p13.2 may be involved (Urbanek, 2005). Further investigation, however, is needed to determine the roles of these gene products in the pathogenesis of PCOS.

PATHOPHYSIOLOGY

Gonadotropins

Anovulation in women with PCOS is characterized by inappropriate gonadotropin secretion (Figs. 17-1 and 17-2). Alterations in gonadotropin-releasing hormone (GnRH) pulsatility lead to preferential production of luteinizing hormone (LH) compared with follicle-stimulating hormone (FSH) (Hayes, 1998; Waldstreicher, 1988). It is currently unknown whether hypothalamic dysfunction is a primary cause of PCOS or is secondary to abnormal steroid feedback. In either case, serum LH levels rise, and increased levels are observed clinically in approximately 50 percent of affected women (Balen, 2002, van Santbrink, 1997). Similarly, luteinizing hormone:follicle-stimulating hormone (LH:FSH) ratios are elevated and rise above 2 in approximately 60 percent of patients (Rebar, 1976).

FIGURE 17-2

Model for the initiation and maintenance of polycystic ovarian syndrome (PCOS). Alterations in pulsatile gonadotropin-releasing hormone (GnRH) release may lead to a relative increase in luteinizing hormone (LH) versus follicle-stimulating hormone (FSH) biosynthesis and secretion. LH stimulates ovarian androgen production, while the relative paucity of FSH prevents adequate stimulation of aromatase activity within the granulosa cells, thereby decreasing androgen conversion to the potent estrogen estradiol.

Increased intrafollicular androgen levels result in follicular atresia. Increased circulating androgen levels contribute to abnormalities in patient lipid profiles and the development of hirsutism and acne. Increased circulating androgens can also be derived from the adrenal gland.

Elevated serum androgens (primarily androstenedione) are converted in the periphery to estrogens (primarily estrone). As conversion occurs primarily in the stromal cells of adipose tissue, estrogen production will be augmented in obese PCOS patients. This conversion results in chronic feedback at the hypothalamus and pituitary gland, in contrast to the normal fluctuations in feedback observed in the presence of a growing follicle and rapidly changing levels of estradiol. Unopposed estrogen stimulation of the endometrium may lead to endometrial hyperplasia.

Insulin resistance due to genetic abnormalities and/or increased adipose tissue contributes to follicular atresia in the ovaries as well as the development of acanthosis nigricans in the skin.

Lack of follicular development results in anovulation and subsequent oligo-amenorrhea.

Note that this syndrome may develop from primary dysfunction of any one of a number of organ systems. For example, elevated ovarian androgen production may be due to either an intrinsic abnormality in enzymatic function and/or abnormal hypothalamic-pituitary stimulation with LH and FSH.

The common denominator is development of a self-perpetuating noncyclic hormonal pattern.

Insulin Resistance

Women with PCOS also display greater degrees of insulin resistance and compensatory hyperinsulinemia than nonaffected women. Insulin resistance is defined as a reduced glucose response to a given amount of insulin. The mechanism of this decreased insulin sensitivity appears to be due to a postbinding abnormality in insulin receptor-mediated signal transduction (Dunaif, 1997). Both lean and obese women with PCOS are found to be more insulin resistant than nonaffected weight-matched controls (Dunaif 1989, 1992).

Insulin resistance has been associated with an increase in several disorders including type 2 diabetes mellitus, hypertension, dyslipidemia, and cardiovascular disease. Therefore, PCOS is not simply a disorder of short-term consequences such as irregular periods and hirsutism, but also one of long-term heath consequences (Table 17-2).

Table 17-2 Consequences of Polycystic Ovarian Syndrome
Short-term consequences 1. Irregular menses 2. Hirsutism/acne/androgenic alopecia 3. Infertility 4. Obesity 5. Metabolic disturbances 6. Abnormal lipid levels/glucose intolerance
Long-term consequences 1. Diabetes mellitus 2. Cardiovascular disease 3. Endometrial cancer

Androgens

Both insulin and LH stimulate ovarian theca cell androgen production (Dunaif, 1992). As a result, affected ovaries secrete elevated levels of testosterone and androstenedione. Specifically, elevated free testosterone levels are noted in 70 to 80 percent of women with PCOS, and 25 to 65 percent exhibit elevated levels of DHEAS (Moran, 1994, 1999; O'Driscoll, 1994). In turn, elevated androstenedione levels contribute to an increase in estrone levels through peripheral conversion of androgens to estrogens by aromatase.

Sex Hormone-Binding Globulin

Women with PCOS display decreased levels of sex hormone-binding globulin (SHBG). This glycoprotein, produced in the liver, binds most sex steroids. Only about 1 percent of these steroids are unbound and thus free and bioavailable. The synthesis of SHBG is suppressed by insulin as well as androgens, corticoids, progestins, and growth hormone (Bergh, 1993). Because of suppressed SHBG production, less circulating androgen is bound and thus more remains available to bind with end-organ receptors. It is for this reason that some women with PCOS will have total testosterone levels in the normal range, but will be clinically hyperandrogenic due to elevated free testosterone levels.

Anovulation

Although androgen levels are typically elevated in women with PCOS, progesterone levels are low due to anovulation. The precise mechanism leading to anovulation is unclear, but hypersecretion of LH has been implicated in menstrual irregularity. In addition, anovulation may result from insulin resistance, as a substantial number of anovulatory patients with PCOS may resume ovulatory cycles when treated with metformin, an insulin sensitizer (Nestler, 1998). Finally, the large antral follicle cohort may contribute to

anovulation. Some patients who have undergone ovarian wedge resection in the past, and more recently laparoscopic ovarian drilling, have found significant improvement in their menstrual regularity. One study demonstrated that 67 percent of PCOS patients developed regular menses following such surgery compared with 8 percent prior to surgery (Amer, 2002).

SIGNS AND SYMPTOMS

In women with PCOS, complaints stem from varied endocrine effects and may include menstrual irregularities, infertility, manifestations of androgen excess, or other endocrine dysfunction. Symptoms classically become apparent within a few years of puberty.

Menstrual Dysfunction

Menstrual dysfunction in women with PCOS may range from amenorrhea to oligomenorrhea to episodic menometrorrhagia with anemia. Chronic estrogen exposure unopposed by the effects of postovulatory progesterone produces constant mitogenic stimulation of the endometrium. The instability of the thickened endometrium results in an unpredictable bleeding pattern. Of note, androgens may counteract estrogen to produce an atrophic endometrium. It is therefore not uncommon to observe amenorrhea and a thin endometrial stripe in PCOS patients with elevated androgen levels.

Characteristically, oligomenorrhea (fewer than eight menstrual periods in 1 year) or amenorrhea (absence of menses for 3 or more consecutive months) with PCOS begins with menarche. However, approximately 50 percent of *all* postmenarchal girls have irregular periods for up to 2 years due to immaturity of the hypothalamic-pituitary-ovarian axis. In girls with PCOS, monthly ovulatory menstrual cycles are not established in the midteenage years, and they often continue to have irregular cycles.

Some evidence suggests that PCOS patients with prior irregular cycle intervals may develop regular cycle patterns as they age. A decreasing antral follicle cohort as women enter their 30s and 40s may lead to a concurrent decrease in androgen production (Elting, 2000).

Hyperandrogenism

Hyperandrogenism is typically manifested clinically by hirsutism, acne, and/or androgenic alopecia. In contrast, signs of virilization such as increased muscle mass, deepening of the voice, and clitoromegaly are not typical of PCOS. Virilization reflects higher androgen levels and should prompt investigation for an androgen-producing tumor of the ovary or the adrenal gland.

HIRSUTISM

In a female, hirsutism is defined as the presence of coarse, dark, terminal hairs distributed in a male pattern (Fig. 17-3). Hirsutism should be distinguished from hypertrichosis, which is a generalized increase in lanugo, that is, the soft, lightly pigmented hair associated with some medications and malignancies. Polycystic ovarian syndrome accounts for 70 to 80 percent of cases of hirsutism, with idiopathic hirsutism being the second most frequent cause (Azziz, 2003).

Women with PCOS typically report hirsutism beginning in late adolescence or the early 20s. Additionally, a variety of drugs may also lead to hirsutism, and their use should be investigated (Table 17-3).

Table 17-3 Medications that May Cause Hirsutism and/or Hypertrichosis

Drug	Brand Name
Hirsutism	
Anabolic steroids	
Danazol	Danocrine
Metoclopramide	Reglan
Methyldopa	Aldomet
Phenothiazines	
Progestins	
Reserpine	Serpasil
Testosterone	
Hypertrichosis	

Cyclosporine	Sandimmune
Diazoxide	Hyperstat
Hydrocortisone	
Minoxidil	Rogaine
Penicillamine	Cuprimine
Phenytoin	Dilantin
Psoralens	Oxsoralen
Streptomycin

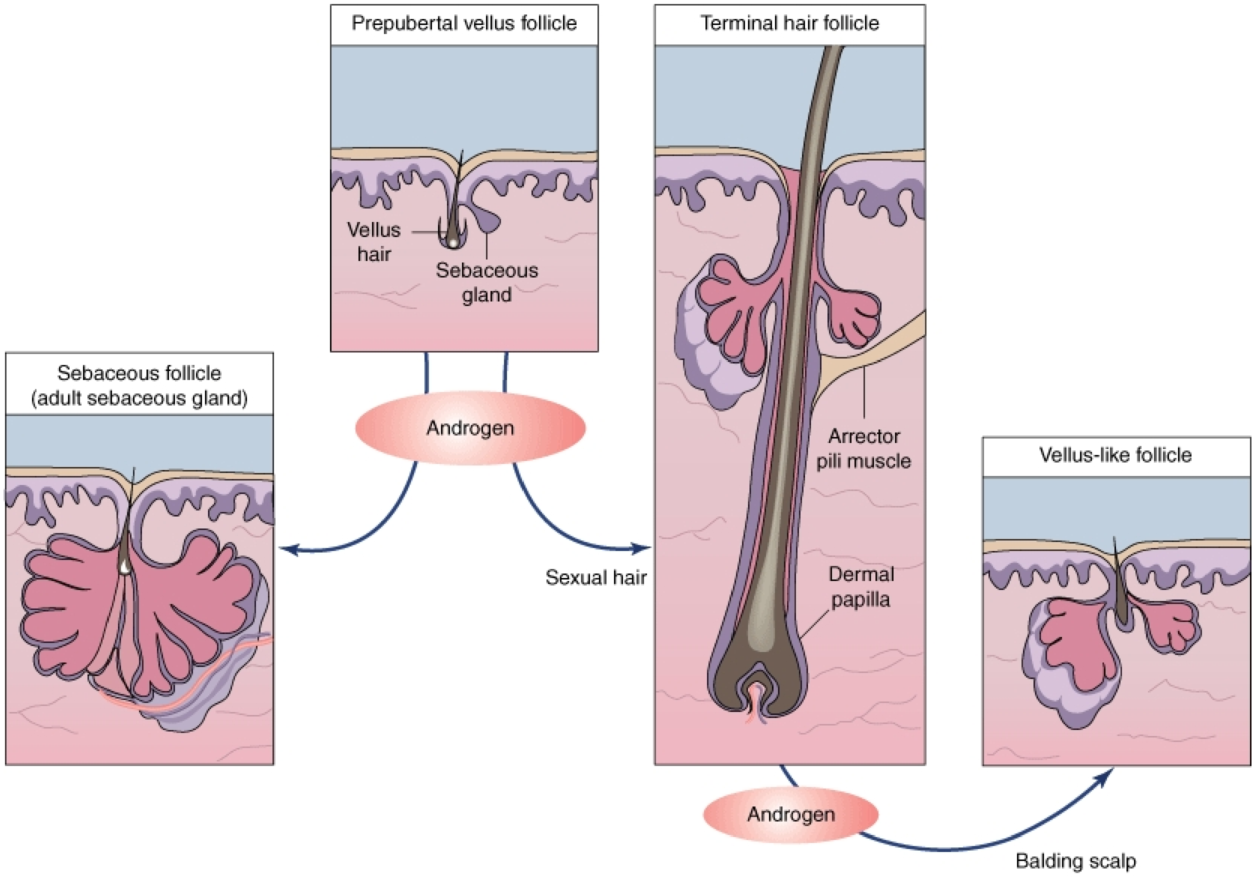
Pathophysiology of Hirsutism

Elevated androgen levels play a major role in determining the type and distribution of hair (Archer, 2004). Within a hair follicle, testosterone is converted by the enzyme 5α-reductase to dihydrotestosterone (DHT) (Fig. 17-4). Although both testosterone and DHT convert short, soft vellus hair to coarse terminal hair, DHT is markedly more effective than testosterone. Conversion is irreversible, and only hairs in androgen-sensitive areas are changed in this manner to terminal hairs. As a result the most common areas affected with excess hair growth in women with PCOS include the upper lip, chin, sideburns, chest, and linea alba of the lower abdomen.

FIGURE 17-4



Androgenic effects on the pilosebaceous unit. In some hair-bearing areas, androgens stimulate sebaceous glands, and increased sebum may lead to acne. In other areas, vellus follicles respond to androgens and are converted to terminal follicles, leading to hirsutism. Under the influence of androgens, terminal hairs that were not previously dependent on androgens revert to a vellus form and balding results. *(From Rosenfield, 2005, with permission.)*

Ferriman-Gallwey Scoring System

To quantify the degree of hirsutism for research purposes, the Ferriman-Gallwey scoring system was developed in 1961 and later modified in 1981 (Ferriman, 1961; Hatch 1981). Within this system, abnormal hair distribution is assessed in nine body areas and scored from 0 to 4 (Fig. 17-5). Increasing numeric scores correspond to greater hair density within a given area. Many investigators define hirsutism as a score of 8 or greater using the modified version.

This system is cumbersome and therefore is not used frequently in clinical settings. Nevertheless, it may be useful in following treatment responses in individual patients. Alternatively, many specialists choose to classify hirsutism more generally as mild, moderate, or severe depending on the location and density of hair growth.

Ethnicity

The concentration of hair follicles per unit area does not differ between men and women, however, racial and ethnic differences do exist. Individuals of Mediterranean descent have a higher concentration of hair follicles than Northern Europeans, and a much higher concentration than Asians (Speroff, 1999). For this reason, Asians with PCOS are much less likely to present with overt hirsutism than other ethnic groups. Additionally, there is also a strong familial tendency for the development of hirsutism, due to genetic differences in target tissue sensitivity to androgens and in the activity of 5α-reductase.

ACNE

Acne vulgaris is a frequent clinical finding in adolescents. However, acne that is particularly persistent or of late onset should suggest PCOS (Homburg, 2004). The prevalence of acne in women with PCOS is unknown, although one study found that 50 percent of adolescents with PCOS have moderate acne (Dramusic, 1997). In addition, an elevation of androgen levels has been reported in 80 percent of women with severe acne, 50 percent with moderate acne, and 33 percent with mild acne (Bunker, 1989). Women with moderate to severe acne have an increased prevalence (52 to 83 percent) of polycystic ovaries identified during sonographic examination (Betti, 1990; Bunker 1989; Jebraili, 1994).

Pathogenesis of Acne

The pathogenesis of acne vulgaris involves four factors, which include: blockage of the follicular opening by hyperkeratosis, sebum overproduction, proliferation of commensal *Propionibacterium acnes,* and inflammation (Purdy, 2006). In women with androgen excess, overstimulation of androgen receptors in the pilosebaceous unit results in increased sebum production that eventually leads to inflammation and comedone formation (see Fig. 17-4). Inflammation leads to the main long-term side effect of acneâ€”scarring. Accordingly, treatment is directed at lowering colonization of *P acnes,* minimizing inflammation, decreasing keratin production, and reducing androgen levels to diminish sebum production (Moghetti, 2006).

As in the hair follicle, testosterone is converted within sebaceous glands to its more active metabolite, DHT, by 5α-reductase. 5α-Reductase has two isoenzymes, type 1 and type 2. Of these, type 1 isoenzyme predominates in sebaceous glands. In skin types prone to acne, such as the face, the activity of type 1 isoenzyme is greater and implies that more DHT is being produced in these sebaceous glands (Thiboutot, 2004).

ALOPECIA

Female androgenic alopecia is a less common finding in women with PCOS. Hair loss progresses slowly and is characterized either by diffuse thinning at the crown with preservation of the frontal hairline or by bitemporal recession (Cela, 2003). Its pathogenesis involves an excess of 5α-reductase activity in the hair follicle leading to a rise in DHT levels. In addition, there is an increased expression of androgen receptors in these individuals (Chen, 2002).

Alopecia, however, may reflect other serious disease. For this reason, affected women should also be evaluated to exclude thyroid dysfunction, anemia, or other chronic illness.

Other Endocrine Dysfunction

INSULIN RESISTANCE

Although not well characterized, the association between insulin resistance, hyperandrogenism, and PCOS has long been recognized. The precise incidence of insulin resistance in women with PCOS has been difficult to discern due to lack of a simple method for determining insulin sensitivity in an office setting. Although obesity is known to exacerbate insulin resistance, one classic study demonstrated that both lean and obese women with PCOS have increased rates of insulin resistance and type 2 diabetes mellitus (DM) compared with weight-matched controls without PCOS (Fig. 17-6) (Dunaif, 1989, 1992).
